ORIGINAL COMMUNICATIONS.

APHONIA.

BY ANDREW H. SMITH, M.D.,

Surgeon to the Throat Department of the Manhattan Eye and Ear Hospital, N.Y.

IN order to the production of a laryngeal sound, two things are necessary,—the passage of a sufficiently forcible current of air through the larynx, and a due approximation and tension of the vocal cords. The first of these conditions is supplied by the action of the chest, and is absent only when there is extreme feebleness of the expiratory muscles, or when the air escapes from the trachea below the larynx, as in tracheotomy. The second condition is much more complex, and may be interfered with in a variety of ways.

The causes of this interference and of the resulting aphonia or loss of laryngeal voice may be divided into those which act mechanically upon the larynx itself, and those which produce paralysis of the muscles of phonation.

When aphonia is due to one of the first class of causes, there exists some departure from the normal condition of the larynx, which presents a mechanical obstacle to the proper approximation and vibration of the cords. The diseased conditions which produce this effect are numerous and varied.

The most frequent is congestion of the larynx from cold. This acts in two ways: first, when the mucous membrane of the cords themselves is swollen, in which case their vibration is interfered with; and secondly, when there is tumefaction of the inter-arytenoid fold, which prevents the approximation of the arytenoid cartilages and consequently of the cords. Tumefaction of the ventricular bands also—which lie just above and parallel to the vocal cords—may cause pressure upon the latter and prevent their vibration. This is not unfrequently the case in acute laryngitis.

Another very frequent cause of aphonia is ulceration attacking either the cords or some other of the movable portions of the larynx. Ulceration of the cords alone in order to produce complete aphonia must be quite extensive. There must be sufficient loss of substance to leave a considerable opening when the cords are approximated to their fullest extent. A less degree will produce hoarseness only. But it generally happens that the same affection which has led to ulceration of the cords has involved other portions of the larynx at the same time, inducing, if not ulceration, at least tumefaction of the mucous membrane. A favorite seat for ulceration is the inter-arytenoid fold already mentioned, where it effectually prevents the folding of the membrane which takes place when the arytenoid cartilages approach each other. This results not only from the tumefaction of the membrane, but from the pain which is felt whenever the ulcer is thus folded upon itself. But the tendency to

aphonia in these cases does not cease when the ulcers themselves have disappeared. In many cases these latter have left behind them an obstacle to phonation quite as formidable as they themselves constituted, in the stiff, contracted, and unyielding cicatrix. Ulcers situated at the anterior extremity of the chink of the glottis and affecting both cords are almost certain on healing to cause adhesion of their edges, analogous to the growing together of the fingers when the skin between them is destroyed by a burn. Situated posteriorly, these cicatrices may drag one or other of the cords out of its natural plane, so that when it approaches the median line it will be above or below its fellow, thus rendering phonation impossible.

Growths of various kinds within the larynx may also be so situated as to prevent a proper approach of the cords. These growths, most frequently polypi or papillomata, are often seated upon the free edge of a cord. In other instances they are just below or just above the cord, near enough to interfere with its action. At other times one of the arytenoid cartilages is the seat of the growth, which impinges against the cartilage of the opposite side before the cords come in contact. In a case which presented itself to me a few weeks ago in the throat clinic at the Manhattan Eye and Ear Hospital, the right capitulum Santorini had assumed the form of a large cuboidal mass, which occupied nearly the whole of the inter-arytenoid space. In this case there had been complete aphonia for a number of years.

Aphonia is also one of the characteristics of that formidable disease—œdema of the glottis. This is in reality a misnomer, for the œdema is not of the glottis, but situated at a considerable distance above it, in the ary-epiglottidean folds. These loose folds of mucous membrane become enormously distended by effused serum, forming large tumors not very unlike sessile mucous polypi. These fall together in the median line, obstructing the ingress of air into the larynx, and of course at the same time destroying the laryngeal character of the voice.

Cases sometimes occur in which ankylosis of the crico-arytenoid articulation prevents the movement of the arytenoid cartilage, rendering impossible a proper approximation of the cords.

Such are the chief causes which, acting upon the larynx itself, present a mechanical obstacle to the formation of the voice.

The treatment of this mechanical form of aphonia is as various as the cause; but in all cases it has for its object the removal of the obstacle to the necessary closure of the glottis.

Simple tumefaction of the mucous membrane from acute or subacute inflammation may be treated by astringent applications with a brush or sponge. Of these the sulphates of copper and zinc, alum, and the perchloride and the sulphate of iron, are especially useful applied in solution. The nitrate of silver has the disadvantage of causing excessive spasm, and, as in most cases equally good effects can be obtained with other applications not open to this objection, it would be better if its use were

reserved for exceptional cases. In the form of spray, however, it is more easily borne, and often produces excellent results. It requires to be used in a very strong solution, sometimes as high as 240 grains to the ounce, and should be thrown directly upon the part.

Much benefit is often derived in these cases from the inhalation of steam containing some soothing medicament. A favorite prescription of Dr. Mackenzie, of London, and one which I have found of great service, is the compound tincture of benzoin. A teaspoonful of this is put into a pint of hot water in a narrow-mouthed pitcher, and the steam is inhaled as long as it continues to come off. When the inflammation is of a more chronic character, inhalations of the stimulating essential oils may be resorted to with benefit. Non-volatile substances, stimulant or astringent, may be nebulized by means of the steam or air atomizers now in such general use.

When the brush is used, I think it well to have the solutions made with glycerin, inasmuch as from its adhesive quality it remains longer in contact with the part, while at the same time its affinity for water makes it a valuable local depletant.

When the inflammation results in œdema of the larynx, scarification after the manner first brought into use by Dr. Buck is the only measure which offers any certainty of relief. As originally performed by Dr. Buck, the operation consists in carrying a curved knife down to the seat of the œdema, using the index finger of the left hand as a guide, and making several scarifications so as to afford a free exit for the serum. Since the introduction of the laryngoscope the mirror has been used to guide the instrument.

Various instruments have also been devised having concealed blades, which are designed to facilitate the operation and render it safer.

The following case illustrates so well the nature of the affection, and also the result of this treatment, that, although the aphonia was a subordinate element in the case, the reader will pardon a momentary digression in relating it.

James Keegan, Ireland, æt. 32, soldier, during the winter of 1861-62 was under my care while lying in camp opposite Washington. He had for months been the subject of syphilitic inflammation of the larynx, and his condition was such that I anticipated the occurrence of œdema at any time when he should be subjected to unusual exposure. One night I was awakened by a strange crowing sound outside my tent, accompanied by a shuffling of feet, and in a moment two men entered, supporting Keegan between them. On striking a light I found him unable to stand alone, his face livid, inspiration exceedingly difficult and accompanied by a loud whoop. He could whisper a few words at a time, but his mind appeared to be wandering. The examination of the throat with the finger was very much facilitated by the frequent manipulations to which it had been subjected in previous treatment. He had acquired the power of opening the mouth to an extent which permitted the introduction of a part of the hand as well as the finger, and the

throat had become so accustomed to the contact of foreign bodies that it could bear any amount of touching without exciting reflex action. These conditions made it very easy to carry the finger down to the larynx and thoroughly examine the parts. The ary-epiglottic folds were found to be enormously distended with serum, the tumors being of the size and shape of small chestnuts. I took a long curved sharp-pointed bistoury and covered the blade with adhesive plaster to within half an inch of the point. Then, using the left index finger as a guide, I had no difficulty in making several thrusts into the œdematous mass. This was followed by the expectoration of a little blood mixed with saliva and serum. The dyspnœa very soon became less urgent, and within an hour the patient was entirely relieved. A few days afterwards the army was transferred to the Peninsula, and Keegan was sent to a general hospital, together with a statement of his case. Soon after I received a piteous letter from him, begging to be returned to the regiment, stating that he had had two attacks of choking less severe than the first one, and that the doctors at the hospital did not know how to relieve him. He added that he was certain he should choke to death sometime if I did not have him returned to my care. This was of course impossible, and a month later I had the pain of learning that poor Keegan's prediction had been accurately fulfilled, he having suffocated in another attack of œdema.

The aphonia which results from loss of substance of the vocal cords is irremediable, but still it sometimes happens that approximation will finally be effected more or less perfectly by a modification of the natural movements of the parts, so that the aphonia will be remedied to a considerable extent.

When the mobility of the cords is restricted by adhesions or by the contraction of cicatrices, the parts may be divided by a cutting operation; but the tendency to heal again in the same way is such as to leave little prospect of ultimate success.

Morbid growths, if not of a malignant character, may generally be removed by evulsion, excision, caustics, or the galvanic cautery. Mucous polypi and papillomata are most readily removed by evulsion with the forceps. A great variety of instruments have been devised for this purpose, which the limits of this paper will not permit me to describe. Harder growths require cutting instruments or the use of caustics or the galvanic cautery. If pedunculated, they may sometimes be removed by means of the laryngeal écraseur.

There is another form of organic aphonia, in which there is no change of form in any of the parts of the larynx, but a paralysis of one or more of the muscles of phonation, owing either to a diseased condition of the muscle itself or to a lesion of the nerves or nerve-centres with which it is related.

The muscles of the larynx are liable to become infiltrated with the products of inflammation; the inflammation arising either in the muscle itself, or, as is more frequently the case, having its origin in the contiguous mucous membrane.

The thyro-arytenoids, lying as they do within a

fold of mucous membrane, we should expect would be more likely to be affected as the result of mucous inflammation than the other muscles of phonation, which are separated by intervening cartilage from any mucous surface; and I have within the present week seen a case of acute laryngitis in which these muscles were paralyzed, causing complete aphonia.

The paralysis of the muscle in such cases will usually disappear as the effused material is absorbed. In some cases, however, this condition is followed by fatty atrophy of the muscular fibre, in which case the paralysis is of course permanent. In other cases a purely functional paralysis remains for some time after the inflammation has disappeared, as will be noticed more fully in another connection.

Paralysis of the muscles may also result from syphilis, diphtheria, lead- or arsenic-poisoning, etc.

The larynx seems, moreover, to be peculiarly susceptible to the influence of irritation in distant parts in which its nerves are not directly implicated, or, in other words, to reflex paralysis, just as we find paraplegia resulting from stricture of the urethra or from the irritation of worms in the alimentary canal. So we may find paralysis of one or more of the laryngeal muscles dependent upon irritation of the abdominal or pelvic viscera. In fact, there is a form of aphonia which derives its appellation from its frequent association with derangements of the uterine function, viz., hysterical aphonia.

But a very frequent source of these paralyses is to be found in an interference with the nervous supply from some cause external to the larynx. This may be a growth pressing upon the recurrent nerve, or the irritation of this nerve, produced by tubercular deposit in the apex of the lung, especially the right.

Again, the paralysis may be caused by disease in the medulla at the origin of the pneumogastric nerve, in which case it will be associated with paralysis of other parts.

There is also another form of paralysis which has no appreciable lesion whatever to account for it, and which gives rise to what is known as functional aphonia.

Whatever the source of the paralysis, aphonia, more or less complete, will be the result whenever the vocal cords cannot be brought together and the proper degree of tension maintained.

The muscles of the larynx may be affected singly or in pairs, and thus we have unilateral and bilateral paralysis of the adductors.

Unilateral paralysis of the adductors is very generally due to some cause located outside of the larynx and affecting the recurrent nerve. This may be a tumor in the track of the nerve, as an aneurism, a goitre, a malignant growth, etc. When this condition occurs on the *left* side, it at once excites suspicion of aneurism of the arch of the aorta at the point where the left recurrent nerve is looped around the vessel.

Occurring on the right side, it is often attributable, according to Mandl, to irritation of the recurrent nerve by the pressure of tubercle in the apex of the lung, the nerve on the right side being in close relation to the pleura. He found the voice affected in fifty out of fifty-two cases in which the right apex

alone was diseased, and in only one out of thirty-two involving the left.

Mackenzie's experience, however, goes to disprove this theory. He found that of seven cases of paralysis of one cord in phthisical subjects six were on the left side.

The poison of lead or arsenic, and also of syphilis and diphtheria, may be confined in its action to one side of the larynx, though its effect is more likely to be symmetrical. The same may be said of disease at the origin of the pneumogastric nerve.

In unilateral paralysis the laryngoscopic appearances are striking and characteristic. When phonation is attempted, one cord is seen to advance to the median line, or perhaps beyond it, while the other remains stationary. Very commonly the paralyzed cord is somewhat congested.

Aphonia does not always result from paralysis of one cord, as the other sometimes moves far enough beyond the median line to meet its paralyzed fellow.

(To be continued.)

THE EXTERNAL EAR A SYNTHETIC RESONATOR.

BY CHARLES H. BURNETT, M.D.,

Aural Surgeon to the Presbyterian Hospital in Philadelphia.

THE auricle, or ear of common language, has usually received but little attention from physiologists. In most cases it is passed by with the vague statement that it serves "to collect sound," or that it exercises "little or no influence upon hearing." The external ear does indeed collect sound, for its function is that of a *synthetic resonator*. It therefore exercises great influence upon hearing, since it insures the proper reception by the auditory nerve of the partial tones composing many sounds produced both by nature and by art.

Before any further explanation of the functions of the auricle, let us briefly consider the acoustic nature of some of the ordinary sounds which are received by it. It is well known that every sound is composed of a collection of "partial tones" or "over-tones" which determine its timbre or clang-tint. Any one of the ordinary sounds of nature, as, for example, the roar of a cataract or of the surf, and the rustling of the leaves in a forest, is composed of a large number of partial tones, which, for the sake of simplicity, let us call deep, intermediate, and high partial tones.

The ordinary normal ear does not isolate any of the partial tones of a composite sound, but perceives them as a whole.

This is due to the fact that certain parts of the auricle resound best to the high partial tones, while other portions of it resound best to the intermediate and low partial tones, thus insuring the complete reception by the auditory nerve of all the partial tones which compose any given sound falling on the auricle. I have discovered by experiments upon my own ear that the region of the helix and its fossa resound to the deeper notes, the antihelix and its fossa to the intermediate notes, and that the concha,

"the deep concavity within the position of the antihelix, presenting a semi-spiral course towards the entrance of the auditory meatus," resounds best to the high partial tones. In order to prove this it is necessary to be in the presence of a sound possessing the characteristics of those already mentioned. By pressing the auricle at its outer edge gently forward, the sound instantly becomes a deeper one, from the augmentation of the resonance for deep tones thus gained by the helix and its fossa.

The deep tones, however, are immediately weakened or lost by placing the finger upon the helix and pressing it firmly against the head. Then we find that the sound becomes one in which the intermediate and higher partial tones are prominent. By pressure upon the antihelix the intermediate tones become weaker, and the higher partial tones are most distinctly perceived, on account of their undisturbed resonance in the concha. Firm pressure upon the helix, antihelix, and concha will interfere with the resonance of all but the highest partial tones. In the latter instance the resonance of the meatus auditorius externus most probably has full scope, for this part of the ear, according to Helmholtz, resounds best to notes of the fourth octave ($e^{iv}-g^{iv}$). Therefore, if any one of these portions of the auricle has its acoustic functions altered, either by disease or artificially, the tones to which it resounds will be weakened or lost, and the prominence of the other partial tones will change the timbre of the original sound.

Experiment will show that by giving prominence to a certain portion of the auricle, viz., the helix and its fossa, a sound may be rendered fuller, and hence louder, from the increased resonance of the deeper notes which enter into its composition. This may explain the asserted increase of hearing in some cases of othæmatoma, when the swelling may have rendered these particular parts prominent and thus have increased their resonating power. But if the disease advances and produces swelling and rigidity of the entire auricle, as it usually does, we can also readily understand the cause of impairment in hearing in these cases.

A man without an auricle can indeed hear sounds, but they are altogether different, acoustically considered, from the complete sounds as heard by the possessor of the normal auricle. In the former case, a large number of the partial tones being lost, the clang-tint of the sound is altered; whereas, in the latter case, when the auricle receives and conveys synthetically all the partial tones to the auditory nerve, the timbre of the composite sound is fully perceived.

NOTE ON A SOLUTION OF IODOFORM.

BY LOUIS ELSBERG, M.D.,

Professor of Laryngology and Diseases of the Throat in the University of New York.

A GREAT objection to the employment of iodoform ($C_2H_3I_3$) in substance is its bad odor, which is very penetrating and persistent; furthermore, there has not hitherto been in use any effect-

ive solution for topical applications in cases where ointments are inapplicable. It will doubtless be of interest to all who know the medicinal value of iodoform to learn that both these objections have been overcome. I have found an ethereal solution which deodorizes iodoform, the solution smelling of ether only, and at the same time constitutes an effective topical remedy for diseased mucous membranes, as of the throat, nose, mouth, larynx, vagina, rectum, etc. Rhighini used an ethereal solution for direct inhalation, and Dr. Sass used an ethereal solution and also a mixture of iodoform and sweet-almond oil by means of a spray-producer for inhalation. Dr. Gubler requested Messrs. Odin and Leymarie to ascertain the relative proportions in which iodoform is soluble in ether, and the most favorable conditions for its preparation; their experiments and conclusions are published in the *Pharmaceutical Journal*, August 2, 1873. The *London Doctor* for September 1 tells us that experiments were made with pure ether of 65° Baumé (specific gravity .724), and also with ether of 62° Baumé and 56° Baumé, the temperature being 13° C. Eight grains of tincture obtained with these ethers contained iodoform in solution, respectively, to the following extent:

Ether of 65° Baumé, 1.61 grammes.

" 62° " 1.26 "

" 56° " 1.13 "

The conclusions drawn by the authors from their experiments are,—

1. To employ iodoform in the crystalline state.
2. To make the solution in a red glass flask by simple agitation.
3. To use the following proportions:

Crystallized iodoform, 1 gramme;

Ether (60° Baumé), 4 grammes.

I had a solution prepared with Squibb's ether, and find that it possesses all the advantages of iodoform in powder for local applications, without its disadvantages. The smarting which the ether may be expected to produce upon the mucous membrane is momentary only, so that the application becomes really painless. Its beneficial effects surpass my expectations.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS, M.D.

Reported by J. B. ROBERTS.

MYOTOMY IN A CASE OF TORTICOLLIS.

A. M., æt. 7, comes before us with wry neck, caused by contraction and rigidity of the right sternomastoid muscle. The head is bent to the right and the face turned to the left, which, from the insertion of this muscle behind the axis of rotation of the head, must always be the result of any shortening of its fibres.

The mother states that the child was born with her head in this distorted condition; but, as cases of congenital torticollis are unusual, we do not receive this statement implicitly.

A strong tense cord is seen extending along the neck,

holding the head firmly in its abnormal position. This is the border of the contracted and indurated muscle, as can be readily proved by tracing it out with the finger.

In this case the employment of extending apparatus for the purpose of remedying the deformity would be of no avail; the only treatment at all practicable is myotomy, or division of the contracted muscular fibres. This operation, as in tenotomy for the cure of club-foot, is done subcutaneously, in order that the air may be excluded and the supervention of a high grade of inflammation prevented. The head of the patient is held by an assistant in that position which will place the muscle on the stretch and make it stand out prominently above the other cervical structures. A delicate knife or tenotome is then introduced at the outer border of the muscle, some distance above its origin, and passed flatwise under it; when the instrument has been carried across, the cutting edge is turned up against the belly of the muscle, which is severed by a sort of sawing motion. Inasmuch as the sterno-mastoid is in relation with important vessels and nerves, the surgeon must be on his guard lest he wound them. With ordinary care, however, he can perform this operation without any danger to these structures.

The rigid fibres, as soon as they have been cut, spring apart, leaving an interval between the ends. Into this space lymph will be poured out, and will finally become converted into analogous tissue, constituting between the two sections of muscle a firm uniting band.

The puncture in the integument shall be covered with adhesive plaster, but there is no subsequent treatment required except rest for a few days in bed. Occasionally it is necessary to use some mechanical contrivance after the operation to keep the head straight until the divided muscle reunites; but here we shall dispense with it, unless we find that from habit the girl continues to carry her head so to one side as to endanger the success of the operation.

LITHOTOMY IN A CHILD THREE YEARS OF AGE

This boy, aged 3 years, has been suffering from symptoms of vesical calculus for the past year, and when he presented himself at the clinic a few days ago had severe neuralgic pains in the bladder; but this trouble has been relieved by the administration of quinine and anodynes.

Upon sounding I readily detect a stone, and shall accordingly proceed to extract it by the lateral operation devised by Cheselden, which method I consider preferable to all others. Before the performance of lithotomy, it is necessary that the patient's rectum be unloaded, so that the bowel may not be wounded by the incision; and it is also important that the bladder contain six or eight ounces of water, to distend and so protect its walls, and to facilitate the removal of the calculus.

Having placed the patient on his back, with the breech brought to the edge of the table, I introduce the staff, which, inclined a little to the right if I cut on the left side, is hooked well up under the symphysis of the pubes, and held firmly by an assistant. In the operation an incision is made through the skin, superficial fascia, and some fibres of the levator ani, and then the transverse perineal muscle, the triangular ligament, the membranous urethra, the prostate gland, and the neck of the bladder are successively divided. The external incision is begun at the raphe, an inch and a quarter above the anus, and extends obliquely to the left, about midway between the rectum and the tuberosity of the ischium, for a distance of two and a half to three inches.

In this child so large an incision is unnecessary, and I shall accordingly make it about an inch and a half in length. Placing my finger in the wound for a guide,

I cut through the tissues mentioned down to the membranous urethra, where I can feel the groove in the staff. After dividing this portion of the urethra I should, in ordinary cases, place the point of the knife in the groove, and push it onward, cutting through the prostate gland and the neck of the bladder; but here I shall merely nick the prostate, and then lacerate it with my finger, so as to have as little hemorrhage as possible, and to lessen the chances of injuring the pelvic fascia. When about to make this cut, I push the rectum to the right with my finger, which has been in the wound all the time, to preclude any chance of injuring the intestine by my knife.

The transverse perineal artery is necessarily divided, but the hemorrhage can be readily controlled. Division of the artery of the bulb, however, is, from the great difficulty experienced in ligating that vessel, a serious complication, which should be carefully avoided.

As soon as the bladder is opened, the urine is expelled with a gush, which generally forces the stone down to the opening, so that it can be seized with the forceps and extracted by gentle traction and rotation. Occasionally the stone gets up behind the pubic symphysis, and can only be dislodged by external pressure over the hypogastrium; at other times, especially when enlargement of the prostate exists, it falls into the cul-de-sac behind that gland, and its seizure is rendered quite difficult.

In this instance the calculus is small, and so soft that it crumbles under the pressure of the forceps; but by using the lithotomy scoop, and washing the bladder out with water from a syringe, I succeed in removing all the particles.

After this operation the urine is usually retained for several hours, when, having accumulated to some extent, it pushes away the clots and forces its way out from the wound with a gush; but its flow is soon checked by the swelling of the parts, and it is compelled to escape by the urethra. In a day or so, however, the tumefaction subsides sufficiently to allow it to pass from the perineal incision, which is its course until the thirteenth or fourteenth day, when it again escapes by the natural channel.

The after-treatment is very simple, and consists in locking up the bowels for several days, and placing the patient on the antiphlogistic regimen.

It is exceedingly uncommon to have union by the first intention after lithotomy, but it does occasionally happen, as is shown by a case that occurred in the practice of Dr. S. W. Gross, where the wound cicatrized without the supervention of the granulating process.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. R. J. LEVIS.

Reported by JOHN B. ROBERTS.

PIROGOFF AMPUTATION AT THE ANKLE—USE OF CARBOLIZED CATGUT LIGATURES.

A MAN was brought to the hospital with his right foot crushed up to near the ankle-joint by the passage of a railroad-train over it. The whole anterior portion of the foot was so mashed that there was no resort but amputation; the only question was as to how much should be removed.

In the surgery of the hand and foot, conservation of the parts should always be an object of the operator, that he may save to the patient all possible utility of the member. The injury here, however, was too extensive to admit of either the tarso-metatarsal (Lisfranc) or the medio-tarsal (Chopart) operation, and therefore the choice was between the tibio-tarsal operations after the

methods of Pirogoff and Syme. The method of Pirogoff, which is a sort of osteoplastic operation, leaves the posterior part of the calcaneum in the flap, to be finally brought into apposition with the lower end of the tibia.

In order to save blood, the tourniquet was applied, not upon the femoral artery in Scarpa's triangle, but near to the injury, so that as little as possible of the limb might be congested by the pressure. An incision was made from the internal malleolus directly around the sole of the foot to the external malleolus, dividing the tissues down to the bone. After the tissues had been pressed backwards as much as possible, the calcaneum was sawed in a direction obliquely upwards and backwards, so that the saw traversed the bone posteriorly to the process called the sustentaculum tali.

Dr. Levis prefers to saw the bone thus, before making the anterior flap and disarticulating the astragalus, because it is firmly held by ligamentous attachments and the saw can be directed with greater accuracy.

The next procedure was to make a slightly-curved dorsal incision, which, beginning at the same point as the plantar, passed across the foot half an inch below the line of the ankle-joint, ending at the external malleolus. Then the joint was entered, the ligaments holding the astragalus to the bones of the leg divided, and the whole of the foot except the heel removed.

Great care was exercised to avoid injuring the posterior tibial artery, for if it had been pierced the flap containing the calcaneum would probably have sloughed. This unfortunate complication can be avoided in most cases by the exercise of caution; though occasionally the extent of injury necessitates the division of the vessel in order to get behind the crushed and lacerated tissues.

After the flaps had been made, a very thin section of the articulating surfaces of the tibia and fibula was sawed off, and the calcaneum brought up into apposition with the freshened bony surface. As there was too much strain upon the flaps, a thin piece was shaved off the tibia a little more obliquely, until the parts came together accurately and without tension.

In arresting hemorrhage, carbolized catgut ligatures were used, as they can be cut off short and left permanently enclosed in the wound; for their animal composition and their antiseptic properties render their presence tolerable to the tissues. These ligatures are made by soaking catgut in a solution consisting of one part of carbolic acid and four parts of olive oil, and are kept immersed until required, that they may be pliable when used. They are preferable to ordinary silk ligatures, which act as setons, preventing the healing of the wound until they are loosened by ulceration. Carbolized catgut is also recommended in ligation of arteries in continuity, because the superficial incisions may be immediately closed, so that immediate union can take place before the artery is cut through by the ligature; then, if a firm clot have not formed, secondary hemorrhage will probably be prevented, and nothing more than a sort of temporary false aneurism result.

The parts were brought together by sutures of silver wire, and adhesive strips were applied over the stump to overcome the action of the tendo Achillis, which sometimes has a tendency to draw the heel upwards, tilting the cicatrix downwards. It occasionally becomes necessary to resort to tenotomy to prevent this occurrence; but it was not required in the present instance.

The great advantages of this amputation over that through the ankle-joint (Syme) are the greater length of the leg, and the retention of the lower surface of the calcaneum and the dense cellular and fatty cushion of the heel, which allows the patient to walk directly upon the stump. The essential difference between these two methods of amputating at the ankle is the removal of

the calcaneum by dissecting it entirely out of the heel flap, in Syme's operation, and the retention of an oblique section of the bone, in Pirogoff's modification.

Pirogoff's method is the more conservative procedure, as it leaves the leg at least an inch and a half longer than it can possibly be after the operation of Syme. In the former, moreover, the tendo Achillis is not cut off and the power of the limb diminished, the heel flap is not cup-like and liable to retain pus, and its vascularity is not injured by dissecting out the bone. The retention of the bone in the flap, with its natural covering of a cushion of integument, produces eventually the most perfect basis for the support of the weight of the body.

This amputation is therefore more generally applicable to cases of injury; but in amputation for chronic disease of the tarsal bones, from the liability of the cancellated texture of the calcaneum to become carious, the entire removal of the bone, as in Syme's method, is usually the more available procedure.

BELLEVUE HOSPITAL, NEW YORK.

POPLITEAL ANEURISM.

J. P., æt. 26, waiter, colored, admitted August 6, 1873, had syphilis eight years ago; with this exception, has always enjoyed good health. Three months ago, patient fell through a hatchway, injuring his back and right leg. Two weeks later, he noticed a feeling of weariness in the right leg and a dull aching pain in the popliteal space. Shortly afterwards he noticed a swelling in this space, of the size of a cherry. This tumor gradually enlarged its growth, causing increased pain down the limb.

On admission, patient is a stout and apparently healthy man. On examination, a pulsating tumor is found in the right popliteal space, of the size of an orange. The pulsation is distensible in character and synchronous with the radial pulse. A double bruit is heard in the tumor. Firm pressure on the femoral artery as it passes beneath Poupart's ligament causes diminution in size of the tumor and cessation of pulsation and bruit; but these return immediately when the pressure is removed. Measurement of the right knee exceeds that of the left by $3\frac{1}{2}$ inches. Digital compression on the femoral as it passes beneath Poupart's ligament was employed, with few intermissions, until August 21, with no apparent benefit. At ten P.M. a shot-bag of ten pounds' weight was placed over the artery, in Scarpa's triangle, assisted by digital pressure. By this means pulsation, etc., entirely ceased in the tumor, and it did not reappear when pressure was removed at the end of ten hours. Repeated examinations failed to detect the slightest pulsation, the tumor remaining firm and solid. Slight pressure was kept up for several days by means of the shot-bag. This continued pressure was well borne by the patient, who said that he experienced very little actual pain.

September 15.—Patient is to-day allowed to sit up out of bed. The tumor is as solid as on the day pressure was discontinued. The leg, which during the time compression was used was cold and required the application of external warmth, has since then resumed its natural temperature. No internal medication was employed.

A case of diffused popliteal aneurism in another ward was treated on essentially the same plan, but with no benefit up to the present.

PELVIC HÆMATOCELE.

A case of extensive effusion of blood in the pelvis, forming a tumor which occupied the hypogastric and iliac regions and extended quite up to the umbilicus,

has been treated by the inunction of equal parts of unguent. belladonnæ and glycerin, hop poultices being applied over this. The relief to pain was marked, and the tumor rapidly softened and disappeared. Internally, iron was given, and an occasional anodyne.

ASPIRATION IN RETENTION.

The following are the notes of two cases in which aspiration was employed to relieve over-distention of the bladder in retention.

Case I.—G. B., æt. 13, three days before admission, slipped from an iron railing on which he was standing, striking on the perineum. He experienced acute pain in this locality, and, shortly afterwards, on attempting to urinate found himself unable to do so. His family physician failed on attempting to introduce a catheter. On admission, patient says that he has not passed water in two days; is suffering very acutely from abdominal pain and desire to micturate; bladder enormously distended, extending above the umbilicus. Perineum red, swollen, and painful. Catheter meets obstruction five inches from the meatus. Dieulafoy's pneumatic aspirator being obtained, a small-sized trocar is introduced in the median line of the abdomen, an inch above the pubes, and a large quantity of urine withdrawn, some being left in the bladder, for fear of hemorrhagic cystitis, which is apt to arise if the bladder be too suddenly relieved of its contents. External perineal urethrotomy was performed, and an extensive rupture of the urethra found at the membranous portion. An incision was made in the wall of the canal anteriorly and posteriorly to the point of rupture. Two months after the operation, the perineal wound had closed, and a No. 10 sound passed without difficulty into the bladder.

Case II.—J. W., æt. 18. Patient states that he had gonorrhœa two years ago. Within last two weeks has had considerable difficulty in passing his water. On the morning of the day of admission he was seized with retention, and when admitted, late in the evening, had not urinated in twenty-four hours. On admission, patient is suffering acutely from constant desire to urinate. A catheter is introduced, passing a slight stricture at the meatus, and meeting obstruction three inches from the meatus at a second stricture. Efforts to pass through this failed, and the patient suffering greatly, the aspirator was employed to relieve him.

Steurer's modification of Dieulafoy's instrument was used, and a large quantity of urine withdrawn, the point of puncture being as in Case I., the patient experiencing immediate relief, unmindful of the slight pain caused by the puncture. A whalebone guide was passed the next day, and forcible dilatation made.

ACUTE ARTICULAR RHEUMATISM.

The alkaline treatment is the one most generally adopted in the medical wards. A prescription which has found great favor is as follows:

R Sodæ bicarb., ℥ss;
Potass. acetat., ℥ss;
Liq. ammon. acetat., f℥ij;
Aquæ, q. s. ad Oj. M.

R Acid. citric., ℥ij;
Aquæ, Oj. M.

℥ij of each q. 3 vel 4 h.

This forms an agreeable effervescing mixture, rendering the urine alkaline very quickly. The frequency with which it is given depends upon the degree of alkalinity obtained as tested morning and evening.

On another division an effervescing draught is made without the addition of the salts of potassa. As a local application, tincture of iodine is sometimes employed. By some the painting is limited to the integument im-

mediately over the joint; by others, the integument corresponding to the blood-supply of the joint, a broad band above and below the joint answering this purpose very well.

Usually, however, cotton dusted with potass. nitrat. and covered by oiled muslin is applied to the joints, affording marked relief. An opiate is given at night:

R Sol. morph. sulph. (Mag.), ℥lxxx;
Tr. belladonnæ, ℥xvj;
Aq. fœniculi, ℥ij. M.

Sig. ℥j p. r. n.

If a friction-murmur develop in the pericardium or pleura, an attempt is made to arrest the inflammatory process by vesication, collodion cum cantharide being used for this purpose. If, however, this fails, hot fomentations are applied to the affected side. Spongio-piline wrung out in hot water and covered with oil silk is generally used. A young girl developed acute pleuritis, left side, and pericarditis, in the course of an attack of rheumatic fever. Spongio-piline applications to the side, changed every two hours, relieved wonderfully the intense lancinating pain she experienced, and appeared to hasten the absorption of the effused fluid. Alkalies were not used in this case. Tr. aconit. rad., ℥j q. i h., was given, modifying the amount of febrile disturbance. The patient rapidly convalesced.

In subacute rheumatism, iron, quinine, and cod-liver oil are given internally, with nutritious diet. Occasional revulsives, as tincture of iodine, are applied, as in the acute disease.

In chronic rheumatism, in addition to tonics, a large number of cases have been treated by painting the joint with hydrarg. et morph. oleatis, most of them receiving considerable benefit from its use, especially in the alleviation of pain.

W. H. FARRINGTON, M.D.

TRANSLATIONS.

UNILATERAL PULMONARY APOPLEXY IN RELATION TO CEREBRAL HEMORRHAGE.

By DR. AUGUSTE OLLIVIER. Translated from *Archives Générales de Médecine*, August, 1873.

BY ENRIQUE M. ESTRAZULAS, M.D.

IN the year 1866, while chief of the clinic of Prof. Grissolle, I was struck by a fact that greatly excited my attention. It was the case of a hemiplegic patient who died, and at whose post-mortem a hemorrhagic clot was found in the cerebrum, with apoplexy of the lung of the paralyzed side, that is, of the side opposed to the cerebral lesion. I then asked myself if there was not a bond of union between these two anatomical lesions, and purposed investigating the subject in future. After two years in charge of the retreat at Ivry, I have had occasion to verify the fact several times, and in the observations reported I have not referred to cases where the pulmonary apoplexy could have been traced to cardiac complication.

True pulmonary apoplexy as it is found in cardiac affections has been almost completely unnoticed by clinical observers, and no mention of it is made even in the latest works on pathology nor in special treatises.

Observation I.—Apoplexy followed by complete paralysis of motility on the right side of the face; complete paralysis of motility of the limbs of that side, and great diminution of sensibility in all the right half of the body. Dulness on percussion on the right lung,

and marked diminution of the respiratory murmur. Intense redness of right half of face shortly before death.

Post-mortem.—*Cranium.*—Vessels of the pia mater full of black blood. The cerebral convolutions offer nothing particular exteriorly, but on section the left corpus striatum is found torn from before backward, containing a clot as large as a nut. Blood has been effused in the corresponding lateral ventricle, which contains about two teaspoonfuls of liquid and black blood, and also a smaller quantity in the fourth ventricle.

Thorax.—Right lung adherent to the thoracic walls, and the seat of intense congestion. On section three apoplectic centres are found as large as a nut, also some emphysema; other organs offer nothing remarkable.

Three peculiarities were offered in this case: 1. Redness of right half of the face shortly before death.

2. Elevation of temperature noted in the right axilla.

3. Congestion and apoplexy limited to the lung in the paralyzed side.

Observation II.—Old hemiplegia of right side; new attack of apoplexy, with aggravation of the paralytic symptoms; paralysis of the right side of the face; paralysis of the limbs on the corresponding side, with contraction of the fingers and forearm; sensibility in the paralyzed side is diminished. Death forty-eight hours after the attack.

Post-mortem.—*Cranium.*—Left corpus striatum torn by apoplexy, and blood effused in the corresponding lateral ventricle, which is found full; right lung congested in all its extent, and underneath the pleura several ecchymoses of variable dimensions are found, and an apoplectic centre as large as a hazel-nut; left lung congested in its inferior and posterior third; other organs healthy.

Observation III.—Several attacks of apoplexy, aphasia and hemiplegia of right side. Death in convulsions.

Post-mortem.—*Cranium.*—On section of the hairy skin the vessels issue a large quantity of black blood. The bones of the cranium are very thick; the groove of the middle meningeal artery is much deeper and wider on the left side; dura mater free from adhesions, its vessels are gorged with blood and appear in varicose arborescences, its color is darkish and almost ecchymotic on the left side; on the posterior part of its left side is a fluctuating elevation, and when incised a sac is found containing about three hundred grammes of dark blood.

This hæmatoma rested on the occipital and parietal faces of the cerebrum, and extended to the fissure of Sylvius. Its walls were easily detached from the dura mater on one side, and from the arachnoid and dura mater on the other. The walls were highly vascular, with a thickness of two millimetres, and their internal surface presented a reticulated appearance. The hemisphere beneath is flattened, and the convolutions effaced. On section the gray substance is found deeper in color than on the other side. The left ventricle has no liquid.

Thorax.—Right lung adherent by old fibrous bands, crepitates badly. Its tissue is dense, and on section it presents a diffused hemorrhagic infiltration, and is studded with numerous apoplectic nuclei of variable size, situated principally in the posterior half. Other organs healthy, except the right knee, which contains some serum, and the cartilage of the patella is found eroded.

Section I.—It results from these observations that, under the influence of cerebral hemorrhage, congestion more or less intense, bloody effusions below the pleura, and true pulmonary apoplexy can be developed. This apoplexy presents itself with the ordinary characters, sometimes diffused and infiltrating the whole organ, sometimes circumscribed and presenting itself under the form of more or less numerous foci situated in the neighborhood of the pleura or in the midst of the parenchyma proper.

In regard to the cerebral lesions causing the pulmonary apoplexy, we notice the following:

They were on the left side. In the first two cases the corpus striatum was torn from before backwards, and the effusion had penetrated the corresponding lateral ventricle, and in one the fourth ventricle also. In the third case there was a meningeal hemorrhage resting on the occipital and parietal faces of the left hemisphere, reaching to the fissure of Sylvius, and the convolutions were effaced.

Of these lesions two peculiarities are noticeable: first, that the apoplectic centre was considerable, and consequently could exert compression on the base of the brain; and, second, that the blood had penetrated under the arachnoid and between the vascular and nervous layers of the pia mater, and on one occasion filled the great cavity of the arachnoid itself. These two conditions appear to me as having great importance in the production of the unilateral pulmonary congestion or apoplexy; inasmuch as in numerous cases that I have observed of cerebral hemorrhage where the lesion was small and deeply situated, I have found but visceral or subcutaneous ecchymoses, and never generalized congestion or true pulmonary apoplexy. It is also probable that other affections of the brain, such as softening or tumors, in *certain conditions of seat and extent*, can produce a strong congestion or true apoplexy of the lung on the opposite side (Fleischman).

Pulmonary congestion and apoplexy of cerebral origin can be rapidly developed and follow an attack of apoplexy. In the first case, dulness was elicited nine or ten hours after the attack, and in the second, dulness and subcrepitant râles were heard the morning following the attack. In these cases, death occurred between two and fourteen days, in consequence of the brain-lesion.

Section II.—We will see now the relative influence of cerebral lesions in the production of hemorrhage, especially in the lungs of the paralyzed side.

It has long been known that section of the pneumogastric, in animals, is followed by bloody effusions in the lungs. Brown-Séquard has also shown the almost constant occurrence of visceral hemorrhage following lesions of certain parts of the base of the brain and of the brain itself. These hemorrhages occur more commonly in the lungs.

Brown-Séquard admits that the rupture of the blood-vessels that originate these hemorrhages is due either to a simultaneous contraction of the veins and arteries, forcing the blood into the capillaries and causing their over-distention and rupture, or, less probably, has been effected by the contraction of the venules alone. Be this as it may, Brown-Séquard thinks that the rupture of the capillaries is due to the irritation of the nerves of the blood-vessels following lesions of the pons Varolii and other parts at the base of the brain. Now to another question on which physiologists are divided:

What is the course followed by the vaso-motor nerves that, starting from the affected point in the brain, go to the lung in which the hemorrhage is produced? Mr. Schiff and Brown-Séquard maintained that these nerves descended with filaments of the pneumogastric; but the latter physiologist has recently shown that after section of the par vagum and irritation of the central ends, pulmonary hemorrhage is produced, while nothing like it occurs if the peripheric ends are excited. He has concluded, then, that the vaso-motor nerves of the lungs, heart, etc., pass through the cervical medulla and the first thoracic ganglion. Moreover, he maintains that the vaso-motor nerves of the thoracic and abdominal viscera do not come from the medulla oblongata, as generally thought, but from the pons Varolii and parts that surround it. It will be seen, then, that the existence of this variety of pulmonary apoplexy that I have studied is demonstrated by clinical observation and physiological experiments, the two fundamental bases of pathology.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 4, 1873.

EDITORIAL.

ANNOUNCEMENT.

THE last issue completed the third year of the PHILADELPHIA MEDICAL TIMES. The editors hesitate to make any promises for the coming year, knowing how often arrangements apparently effected fail in their accomplishment: it seems, however, proper to state that original communications are promised by leading physicians in London and Edinburgh; that the staff of American contributors has increased; that a competent physician has gone to Paris to report clinical lectures by professors of l'École de Médecine, and to furnish notes of the doings of the various societies and of the hospital practice; that the London letter will appear regularly; that a correspondence is promised from Vienna; and that at home the practice of the New York and Philadelphia hospitals will be reported.

This journal was not inaugurated for the purpose of making money, but was the outcome of a need felt by the medical profession. Born of the profession, it should be maintained in the interest of the profession. We are profoundly convinced that, given a sufficiently large subscription-list, it can be made to take rank with any journal of its class in the world; and as the income increases the publishers promise to increase the size of the journal, or in other way expend upon it moneys received. We pay for all original papers deemed worthy of publication, and for contributions of especial value we will continue, as we have done in the past, to pay especial rates.

YELLOW FEVER.

ALL of our readers have of course heard of the frightful epidemic of yellow fever which has depopulated the little city of Shreveport, driving away one-half of its population and killing ten per cent. of the remainder. Like most other similar visitations, this one is the result of a total neglect of all sanitary rules. Shreveport is the second city of Louisiana,—the great trade centre of the Red River country, so famous for its cotton and sugar,—and is estimated to have a population of from 10,000 to 13,000. It is on the Red River, at the head of steamboat-navigation, and fifteen miles below the great Red River raft, which is one of the most remarkable formations in the world, being a mass of logs and drift-wood over forty miles long, and entirely choking up the great stream, which is over twelve hundred miles long, or, including the South Fork, twenty-one hundred. This raft turns the water of the river over the adjacent country, forming great bayous, through which, at high water, steamboats pass around the raft; and it is now being blasted away by the general government.

The city is on a bluff at the river-bank, and is well situated for drainage. The whole country around is flat, and for miles and miles there is one continuous succession of marshes, swamps, and bayous. Though at low water a great surface is exposed to the action of the sun, making the surrounding country subject to malarial influences in the hot season, still the health of the city has generally been good; but this is the third time it has been visited somewhat severely by the yellow fever, the first time having been in 1853, and the second in 1867. It seems that, owing to the contending factions which have reduced the government of Louisiana to chaos, and which would have brought about a Mexican-like civil war had it not been for the strong arm of the federal government, Shreveport has been for some months without a regular municipal government. Those having control of the city have been utterly negligent of their duty, and have left the streets in an indescribably filthy condition. Under the hot semi-tropical sun, the reeking heaps of garbage, the swollen, bursting carcasses of all sorts of animals, the stagnant pools full of all uncleanness, have become the resting-place of the poison. Filth and exposure begot recklessness, and recently a most extraordinary attraction was added to the already too pressing invitation to epidemic disease. It is said (*Vicksburg Herald*) that a boat, having on board a hundred or more Texas cattle, recently sank in the Red River, very near to

Shreveport, and the dead animals were fished from the wreck and taken ashore. After having been skinned for their hides, the bloated bodies were permitted to remain exposed to the rays of a burning sun, until they poisoned the air with their sickening effluvia. Under these circumstances, is it a wonder that another tale of sorrow and desolation, another frightful warning, has been added to the long list, which should teach the world, if it would only learn, the importance of sanitary science?

AS most of our readers no doubt know, some years since there was inaugurated by law in the province of Ontario, Canada, a general medical board or council, before which all persons desirous of practising medicine in the province had to appear and undergo an examination. This licensing board has always reminded us of Barnum's happy family, since upon it regulars, homœopaths, and eclectics sit in sweet accord. Strict written and oral examinations have been enforced by this board, the candidate passing first upon those branches supposably common to the three schools, and then being examined in therapeutics according to his wishes as to his future practice.

However strange and repulsive this mixture of Jew and Gentile, of science and impudence or insanity, may appear, the process prescribed by the law really seems to have wrought great good. The compulsory study of a scientific groundwork, the side-by-side contrast of truth and falsity, have had such marked results that during the last nine years not a single homœopathist or eclectic has passed as such in the province, so that the chief of the homœopathic division has recently withdrawn from the council, and is seeking the repeal of the law under which it was created.

IN a discussion before the Medical Society of the County of Kings, New York, reported in *The Sanitarian* for October, Dr. A. N. Bell remarked,—

"He knew of but one antidote to the reproduction of fungi, and that was fungi. Naturalists tell us that the 'fairy rings' of the prairies are caused by fungi, and in this wise: they attack and destroy the grass at a central point, spreading out on all sides, leaving the ground bare. After a time, when the fungi have totally disappeared from the point first attacked, grass seeds again take root, and, spreading outwards from the centre towards the expanding border, form the ring. And the singular feature is, that the same place is not again subject

to attack: the fungi have poisoned against themselves.

"This natural history of the fungi in the prairies bears a singularly interesting analogy to the results of certain zymotic diseases. They poison against themselves; and whether this peculiarity is due to the nature of the germ or not—and that it is a fungus he would not undertake to say—one thing, at least, is certain, it acts very much like it."

The fact asserted by Dr. Bell is very curious, and we would like to know upon whose observation it rests,—how a given spot was marked, and how long it was watched. Indeed, at present the statement cannot be accepted as true in its fullest extent. It may, however, be acknowledged that the fungi will not grow for some time on the ground which they have gone over; but that this is due to their poisoning against themselves seems a most unwarrantable conclusion. Fungi feed on organic matter; certain species affect certain forms of organic matter. The fairy fungus eats up its peculiar food, and the soil, being exhausted, is no longer able to sustain the parasite. No doubt if the soil be allowed to rest long enough in its wild uncultivated state, it will recover itself. At least, so we reason.

THE effect of custom in affecting our sensibilities is a strange thing. With us it is considered *infra dig.* to contract for medical services to families at so much a week, month, or year, whilst to receive a fixed fee per visit is completely *en règle*. In India things are contrariwise; and concerning the proposition to have regular fees, so much a visit, the *Indian Medical Gazette* editorially discourses as follows:

"We have received a circular from a brother officer, in which he proposes to supersede the time-honored contract system by a scale of fees per visit, arranged according to salaries. This would necessitate the keeping of accounts and the submitting of bills. There seems to be but one step between this sort of thing and the shop,—the lowest form of medical practice. It would be demoralizing in the extreme to associate every particular act of attendance or service on the part of the doctor with a sum of money, in most cases trifling; and nothing could be more humiliating than the necessity of annually, or at the end of a protracted attendance, presenting a grateful patient or sorrowing relative with something like the following:

JOHN JONES, JOINT MAGISTRATE OF STINKABAD,		Dr.	
To SURGEON-MAJOR PHILIP GRAB,			
Civil Surgeon of Stinkabad,			
		Rs.	As. P.
To 25 visits, @ Rs. 5		125	0 0
" 5 night do., @ Rs. 10		50	0 0
Total		175	0 0
		E. & O. E.	
		Received payment,	
		P. GRAB.	

"Nothing would more effectually smother the nice feeling which ought to exist between a doctor and his patient than this sort of thing; a medical man would even feel a delicacy in paying a second visit to a sick person, however necessary he might consider it, unless specially sent for."

IT is stated that the tops of the Ornithogallum pyrenaicum have come largely into use at Bath, England, as a substitute for asparagus.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPTEMBER 11, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. W. G. PORTER exhibited for Dr. Milner the *urethra, ruptured bladder, ureters, and kidneys* of a dog. The dog was brought to Dr. M. with apparent retention of urine. A post-mortem examination revealed a calculus in the urethra, which had so effectually occluded the canal that the accumulation of urine finally caused a rupture of the bladder. The stone was lost.

Dr. JAMES TYSON presented a specimen of *aneurism of the abdominal aorta* from Geo. W. E., aged about 50 years, who was admitted to the Philadelphia Hospital in the latter part of August, complaining of pain in the left lumbar region, which, however, received little attention, as the man was thought to exaggerate his suffering. He therefore obtained little sympathy. He said he had had syphilis many years ago, and attributed all his suffering to this cause.

His complaint continuing, a physical exploration of his abdomen revealed dulness throughout the left hypochondriac and lumbar regions. A cystic kidney was thought of, and the urine was carefully examined, but found free from pus or albumen.

On the 1st of September a more careful physical exploration was made, when it was found that dulness began laterally at the sixth rib and extended to the crest of the ilium. The axilla above the sixth rib was normally resonant. The epigastric region on light percussion was tympanitic; to a forcible blow there was dulness. The dulness of the left lumbar region extended to the median line. The iliac region responded normally to percussion. Posteriorly, percussion was dull from the spine of the left scapula to the crest of the left ilium. In the infra-spinous fossa there was bronchial breathing; below the scapula the respiratory murmur was feeble, and vocal fremitus was almost absent, also laterally below the sixth rib.

The patient now had a very frequent, feeble, and irregular pulse, but his skin was warm, and there were no symptoms of collapse. He complained of pain throughout the area of dulness, but could sit up without any difficulty or distress in breathing. No impulse was at any time observed, and auscultation of the abdomen was not thought of.

On September 3, the left half of the abdomen and the lower third of the thorax were much swollen, the point of culmination appearing to be in the vicinity of the floating ribs. This area was hard, flat on percussion, and purplish in hue. The patient was now evi-

dently in collapse, and died at five o'clock this day, the last examination having been made about noon.

The post-mortem examination was made fifteen hours after death. The region alluded to in the last note as the seat of dulness and hardness had become soft, and the intercostal spaces, which were almost obliterated, were then distinct. On making the abdominal section, the space between the muscles and fascia was found infiltrated with blood. On laying back the abdominal walls upon the left side, this infiltration was noticed forming a clotted mass in the situation of the abdominal walls over the left iliac fossa. There was also observed a tumor occupying the left hypochondriac and upper part of the left iliac region, encroaching somewhat upon the thoracic space, so that the lower edge of the left lung corresponded with the fifth interspace. To the left side of the tumor was attached the descending colon. On the upper and outer surface lay the spleen, which was of normal size and consistence; on the antero-lateral surface of the tumor lay the left kidney, much enlarged, measuring five inches in its longer diameter and two and a half in its width.

Further exploration revealed this tumor to be a huge clot beneath the peritoneum, continuous at its upper portion with an opening in an aneurism of the aorta below the diaphragm. The sac was four inches in diameter, and lined with plates of calcareous matter. Anteriorly from the aneurism protruded a prominence which resembled the head of the pancreas and was perforated by a blood-vessel of considerable size. This, on section, proved to be an organized clot made up of numerous concentric layers of fibrin, by which the anterior wall of the vessel was greatly strengthened, rendering rupture in this situation impossible. The aneurism was therefore compelled to yield at a weaker point, which was on its left inferior aspect. The firmness of the large clot led the doctor to believe that the hemorrhage had ceased for a time; that is, the clot had closed the orifice of rupture, after which the man lived in the feeble but not collapsed state alluded to as present two days before death. A yielding of the clot finally permitted the hemorrhage which caused his death, and which produced the liquid infiltration and mass of semi-liquid or imperfectly coagulated blood in the abdominal wall between the muscles and peritoneum and over the left iliac fossa. There was caries of the bodies of the lumbar vertebrae.

Dr. C. B. NANCREDE referred to a case of aneurism of the abdominal aorta in which there had been profuse diuresis, and desired to know whether it was present in this instance. Dr. TYSON replied that none had been observed.

Dr. ALLIS referred to an autopsy at which he was present. The case presented during life a solid tumor extending from the diaphragm to the pelvis and lying on the left side of the vertebral column. It was attended with excruciating pain, and the relief the patient experienced from morphia was so complete that he was suspected of malingering. The case was under observation for about a month, and abscess of some deep structure was suspected. No suspicion of aneurism was entertained.

Dr. ALLIS did not see the case during life, and would ask the Society what effect aneurism of the abdominal aorta would have upon the pulsation in the femoral arteries.

The PRESIDENT said that a *retarded beat* in the femoral was expected in affections of this kind.

Dr. WHARTON SINKLER exhibited a specimen of *aneurism of the ascending aorta*, from J. G., colored, æt. 66 years, married, and of temperate habits. He was by occupation a coachman, but for twenty years had had no regular employment, and had done light work of any kind. In 1848 he sustained a compound frac-

ture of the leg, and was in the Pennsylvania Hospital a year, at the end of which time the leg was amputated just below the knee. The stump healed rapidly, and has never given any trouble. With the above exception, he had always enjoyed good health. Never had acute rheumatism, but had occasionally pain in the shoulder or knee.

Two years ago, he began to have slight attacks of dyspnœa on exertion; had no palpitation of the heart or other symptom of disease of that organ. Had never had precordial pain.

About one year ago, he had a violent and alarming attack of dyspnœa. Stimulants and a hypodermic injection of morphia very promptly relieved the symptoms, and for several months the patient enjoyed good health, with the exception of occasional paroxysms of dyspnœa.

A physical examination revealed a loud blowing murmur at the base of the heart, coincident with systole.

The murmur was transmitted along the course of the aorta and the carotids. There was no visible pulsation of the superficial arteries. Urine was scanty, and contained about one-third albumen. No microscopical examination was made.

About the beginning of April, 1873, a pulsating tumor, about the size of a pigeon's egg, was observed just above the sternal end of the left clavicle. There was no thrill distinguishable in it, but on placing the stethoscope over the swelling the aortic murmur was distinctly heard. The tumor increased gradually in size, and finally the clavicle was elevated by it to a marked degree. There was no dysphagia or aphonia.

On May 19, sphygmographic tracings were taken of the right and left radials. There was a modification in the trace of both radials, but the right indicated a more oblique line of ascent and a more rounded apex-curve.

During the last five months of his life there were general anasarca and some peritoneal effusion. There was also some œdema of the lungs.

Diuretics and purgatives were used, but without relief to the dropsy, and the patient gradually became weaker, and died August 20, 1873.

Post-mortem, thirty-two hours after death.—Rigor mortis marked. Considerable deposit of fat in superficial fascia. Cartilages of ribs ossified. Pleural and abdominal cavities contained a moderate quantity of fluid. Lungs congested. Heart dilated and walls thin. Pericardium adherent to heart throughout, but easily detached. No disease of valves, except a slight thickening of the aortic valves.

Arch of aorta enlarged to double its usual size. Its inner surface was roughened, and covered with patches of atheroma and calcareous plates. The innominate artery was greatly enlarged, the dilatation extending to the carotid and subclavian for about two inches.

The left carotid and subclavian arteries were not materially increased in size. The kidneys were small, but did not appear diseased.

Dr. C. H. BURNETT presented a bean from the honey locust-tree, removed from the ear of a boy æt. 13 years. There was every reason to believe it had been introduced two years ago. The boy consulted him not with regard to this ear, but for some pain in the other; and it was only on examining the ear for another purpose that he discovered the foreign body. It was removed without any difficulty. Indeed, Dr. Burnett had never met any difficulty in removing foreign bodies from the ear when they had not been previously manipulated by the laity or sometimes by medical men.

The bean was in a perfect state of preservation, and the boy said he had been induced to introduce it from having seen the same thing done by older boys, who pretended to remove the foreign body through the nose.

TWENTY-FIRST ANNUAL MEETING OF THE AMERICAN PHARMACEUTICAL ASSOCIATION.

HELD AT RICHMOND, VIRGINIA, SEPTEMBER 16, 1873.

Reported by ADOLPH W. MILLER, M.D.

PRESUMING that the transactions of this body, which bears so close a relation to the medical profession, may be of interest to some of your readers, venture to offer the following epitome of the proceedings, which have just been brought to a highly successful termination. The attendance of members at this, the first meeting of the Association in a Southern city, was larger than usual. All the deliberations were carried on in a very orderly, decorous, and business-like manner, and they were attentively listened to by the assembled pharmacists, many of whom were accompanied by their ladies.

The meeting was called to order on Tuesday, the 16th ult., at three o'clock, by President Albert E. Ebert, of Chicago, Illinois. He stated in his introductory remarks that at the same moment the Austrian Apothecaries' Association was in session in Vienna, and the British Pharmaceutical Conference at Bradford, England, from the latter of which he read a telegram of hearty greeting, to which he had replied as follows: "We return your fraternal greetings."

The mayor of the city of Richmond, A. M. Keiley, Esq., was then introduced to the audience. He congratulated the Association on its having attained its majority in that city, and proposed that its members be naturalized and remain evermore citizens of the Old Dominion. In concluding his happy and very appropriate address, which was received throughout with cheers, he dwelt on the good taste shown by the visitors in bringing with them the fair representatives of their hearths.

The important event of the second session, on Wednesday morning, was the election of officers for the ensuing year, resulting as follows:

President,—John F. Hancock, Baltimore.

First Vice-President,—William Saunders, London, Ontario.

Second Vice-President,—John F. Buck, Jackson, Mississippi.

Third Vice-President,—Paul Balluff, New York.

Treasurer,—Charles A. Tufts, Dover, New Hampshire.

Permanent Secretary,—John M. Maisch, Philadelphia.

Reporter on the Progress of Pharmacy,—C. Lewis Diehl, Louisville, Kentucky.

The Standing Committees on the Drug Market, on Papers and Queries, on Business, on Unofficial Formulas, on Legislation, on Liquor-Dealers' License, on Stamp Tax, and on the Meeting in 1876, were also confirmed; after which the treasurer made his report, showing a balance of \$982.77 on hand.

Professor Ebert, of Chicago, had in store a very agreeable surprise, consisting in a donation of five hundred dollars to the Association. In the modest note accompanying his munificent gift, he desired the annual interest of the fund to be devoted to procuring a suitable prize for the best essay containing original investigation of a medicinal substance, determining new properties, or containing other meritorious contributions to knowledge. Thanks befitting the occasion were offered to the donor, and it was at once decided to designate the present as the Ebert Fund, and its interest as the *Ebert Prize*.

Prof. Diehl presented a report detailing a plan for an international pharmaceutical congress, to be held in Philadelphia in 1876.

A number of valuable papers were read in the course of the morning. Among them were several of more

than usual interest, by Dr. Squibb,—one of these a new style of physicians' pocket-cases, whose peculiarity consists in being furnished with an accurately graduated minim pipette, which can be dipped into each of the vials, thus materially facilitating the administration of small doses of powerful remedies. The cases are made of different sizes, some of them being furnished with clasps, while others are arranged as slides. Obstetrical cases for fluid extracts of ergot and veratrum viride and denarcotized tincture of opium, with measuring pipette, were also shown, and it was stated that these are very popular in New York City.

Prof. G. F. H. Markoe, of Boston, read a lengthy review of the United States Pharmacopœia of 1870, in which he called attention to a number of inaccuracies, and severely criticised some of the processes. He particularly deprecated the plan of making so many of the fluid extracts by a set schedule, and desired a separate formula for each of them.

The morning was chiefly occupied with the reading of scientific papers, one of the most important being the official report of Prof. Hancock on the unofficial elixirs. His paper was accompanied by some very elegant specimens of his elixirs, for all of which he gave succinct and readily executed formulæ.

Prof. Maisch then offered a resolution recommending that these formulæ be used by the members of the Association, and that a printed copy be sent to the medical societies of the Union, with a request that physicians, when prescribing elixirs, would give preference to these.

Prof. Maisch showed some muriate of cinchonia which had been sold to Mr. G. I. Luhn, of Charleston, South Carolina, as sulphate of quinia, by a notorious New York firm: it had been put up in imitation of imported French quinia, and was sold a trifle below the price of the domestic article.

A resolution tendering the hearty thanks of the Association to the pharmacists and citizens of Richmond, for the cordiality of the reception at this its first visit to the Sunny South, preceded the final adjournment.

Pharmaceutical Exposition.—Perhaps the most inviting and instructive feature of the meeting was the exhibition of drugs, chemicals, apparatus, and other objects of interest to pharmacists. Of the many interesting objects space is wanting to notice more than a few.

As usual on similar occasions, the finest and largest collection of choice chemicals was exhibited by the renowned Philadelphia firm, Messrs. Powers & Weightman. One of their bell-glasses contained about \$1300 worth of morphia, and another about \$800 worth of quinia, the entire value being nearly \$5000. Rosengarten & Sons presented a good assortment of fine chemicals, also a handsome specimen of cultivated cinchona-bark from the government gardens at Ootacamund in India.

Charles T. White & Co., of New York, made an elaborate display of raw chemicals; they make a specialty of resublimed carbonate of ammonia, and very pure acetic acid, which enable druggists to furnish the liquor ammonii acetatis entirely free from empyreumatic taste.

Lazell, Marsh & Gardiner, of New York, displayed true Pareira brava, agreeing with the description recently published in the English journals; Austrian rhubarb from Rheum Rhaponticum, which has lately been rejected by the New York Custom-House; Persian opium, a new sophistication, being an extract made of the entire poppy capsule.

Hance Bros. & White, of Philadelphia, made decidedly the finest and most ornamental display in the room. Their very numerous preparations were elegantly put up in engraved bottles, mounted on a beautiful black-walnut stand.

Ira W. Blunt, of Richmond, Virginia, was almost constantly on hand to explain the merits of Valentine's meat-juice. The superiority of the domestic meat-extract is claimed to be due to the low temperature used in its evaporation, which never exceeds 130°, so that the albumen is not coagulated, but is retained in its natural state.

Dr. James B. McCarthy, of Richmond, offered seven specimens of native wines made at his vineyards in Henrico County, each of them accompanied by the grapes from which it is manufactured. These wines, being perfectly pure, having a pleasant taste, and being offered at comparatively low prices, deserve a favorable recognition by the profession.

Good, Roof & Co., of New York, exhibited elixir de Vichy, imported from France. This claims to be prepared by concentrating Vichy-water and then flavoring with an aromatic cordial.

S. Mason McCollin, of Philadelphia, showed watch-spring pessaries made in an improved manner by the Breed process.

Oscar G. Crosby, of Richmond, Virginia, had on exhibition a model of an improved invalid's bedstead, invented by himself. It is furnished with a crank for elevating the upper half of the bottom to any desired angle, at which it can be kept stationary; also a crank for lowering the mattress without disturbing the patient, and one for moving and fixing the foot-rest to wherever it may be most convenient. There is an additional arrangement for lowering the lower half, so that the whole bedstead becomes converted into a reclining chair. It is apparently a very useful, and certainly is a highly ingenious, invention, though, like many similarly complicated appliances, it may possibly soon get out of order.

REVIEWS AND BOOK NOTICES.

SMALLPOX, FROM AN EPIDEMIOLOGICAL AND PROPHYLACTIC STAND-POINT. By DR. LEON COLIN, Physician-in-Chief of the Military Smallpox Hospital of Bicêtre during the Siege of Paris, 1870-1871, etc., etc. (La Variole au Point de Vue épidémiologique et prophylactique. Par LEON COLIN, Médecin principal de l'Armée, Professeur à l'Ecole d'Application de Médecine militaire (Val de Grâce), Médecin-en-chef de l'Hôpital militaire des Varioleux de Bicêtre pendant le Siège de Paris, 1870-1871. Paris, J. B. Baillière et Fils, 1873, pp. 158.)

In this well-written monograph Prof. Colin gives us the results of his experience in the epidemic of smallpox which prevailed so extensively in Paris at the time of the German invasion of France; and, as the field of observation was, unfortunately, very ample, comprising nearly eight thousand cases and over one thousand deaths in a period of about six months, the conclusions at which he arrived are eminently valuable.

As it would be impossible to reproduce these, however, in the short space allotted for this notice, we will content ourselves with mentioning that in regard to animal vaccination, of late so warmly discussed, Dr. Colin states that out of one hundred and twenty of the hospital attendants vaccinated in his presence, from a heifer, not one contracted smallpox, although living so constantly in the atmosphere of contagion; and in reference to the isolation of smallpox cases, Dr. Colin asserts that in spite of the overflowing condition of the wards of Bicêtre, where twelve hundred variolous patients were crowded together for several months, no perceptible aggravation of the disease in consequence of the accumulation of poisonous emanations in the circumambient air could at any time be detected.

THE EFFECTS OF HIGH ATMOSPHERIC PRESSURE, INCLUDING THE CAISSON DISEASE. By ANDREW H. SMITH, M.D., Surgeon to the New York Bridge Company, Member of the Academy of Natural Sciences, Philadelphia, etc., etc. Being the Prize Essay of the Alumni Association of the College of Physicians and Surgeons. New York, 1873, pp. 53.

However true, as a general rule, may be King Solomon's assertion that "there is no new thing under the sun," we certainly seem to have, in the subject of this memoir, a novel malady, which former ages never inflicted upon mankind. From the "caisson," this Pandora's box of the nineteenth century, appears to have issued, to quote Dr. Smith's definition of the complaint which he has the honor of naming, "a disease depending upon atmospheric pressure, but always developed after the pressure is removed. It is characterized by extreme pain in one or more of the extremities, and sometimes in the trunk, and which may or may not be associated with epigastric pain and vomiting. In some cases the pain is accompanied by paralysis more or less complete, which may be general or local, but is more frequently confined to the lower half of the body. Cerebral symptoms, such as headache and vomiting, are sometimes present. The above symptoms are connected, at least in the fatal cases, with congestion of the brain and spinal cord, often resulting in serous or sanguineous effusion, and with congestion of most of the abdominal viscera."

In the treatment of these cases, whereof thirty are recorded, Dr. Smith relied chiefly on morphia and atropia, by the mouth or hypodermically, and the administration of Squibb's fluid extract of ergot in teaspoonful doses. Some judicious suggestions in regard to prophylaxia conclude the report.

A MANUAL OF MEDICAL JURISPRUDENCE. By ALFRED SWAINE TAYLOR, M.D., Fellow of the Royal College of Physicians, and Professor of Medical Jurisprudence and Chemistry in Guy's Hospital. Seventh American Edition. By JOHN J. REESE, Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania.

Every system of morals inculcates respect for gray hairs; and when a book has reached the hoary age of the seventh edition, let the critic fondle it lovingly if he like, but let him beware how he raise an irreverent hand against the work anointed by the profession. In the presence of the general verdict, we deem it best to keep silence, and merely in a few words inform our anxious readers what has happened to their favorite in this its sixth regeneration. Well, the high priest of the ceremonial has been Prof. Reese, and he appears to have done his work judiciously,—we may say lovingly. To aid him he has had the advanced sheets of the still parturient London edition of the author's great work on the Principles and Practice of Medical Jurisprudence, and has availed himself of it by incorporating much new matter from it into the text of his bantling. Several subjects not treated of in the former edition are discussed in this one; and we doubt not that the work will continue to enjoy the sunshine of success and of professional favor.

NATURE IN DELIRIUM TREMENS.—Dr. Van de Warker believes (*New York Medical Journal*, August, 1873) that opiates, stimulants, and narcotics generally do harm in the treatment of delirium tremens, and that the proper plan is to provide for the nutrition of the impoverished brain and nerve-centres, by the free administration of food which can be easily digested and assimilated. Beef-tea, raw eggs, and milk, with attention to the condition of the bowels, have given him very satisfactory results.

GLEANINGS FROM OUR EXCHANGES.

WOUND OF THE LIVER (*Chicago Medical Journal*, September, 1873).—Dr. G. W. Stewart reports the case of a farmer's boy, æt. 17, who was knocked down by a runaway team in front of his plough, the point of which struck him in the back. It inflicted a wound eleven inches in length, extending from the fourth to the first lumbar vertebra, in the left hypochondriac region, engaging the twelfth rib and denuding it of its periosteum in the anterior third, passing through the peritoneum, entering the liver at the left lateral ligament and proceeding in the direction of the intersection of the longitudinal with the transverse fossa, within which, and only a few lines beyond the terminus of the incision, could be distinctly felt the hepatic artery. Nearly or quite all of that portion of the left lobe of the liver anterior to the incision was found protruding through the wound. The case was seen about two hours after the accident; hemorrhage had ceased, but the patient was nearly comatose from want of blood, a large quantity of which was removed from the abdominal cavity with a sponge: the stomach was empty and had escaped injury, as had also the intestines, diaphragm, and other organs. The abdominal aorta could be distinctly felt in the floor of the wound.

The protruding portion of the liver was replaced with some difficulty, and retained by a compress and a wide roller bandage; cold water was applied to the wound, which was closed up, the patient was placed on a bland and restricted diet, and small doses of opiates were administered. The compress was removed at the end of twenty-four hours, but no other change was made for some time. The wound began to discharge pus freely about the sixth day, the patient gained strength from the first, and no indications of peritonitis appeared at any period. About the twelfth day the flaps sloughed off and exposed to view the liver and also the twelfth rib. A portion of the former equal in size to a two-inch cube was again protruding through the wound, and was irreducible, owing to adhesions between the borders of the left lobe and the abdominal wall. Caustic was applied daily, and the cauterized material afterwards removed with a knife, until the prominence had disappeared. About one-half of the exposed and projecting rib was then removed with bone-forceps. The wound then improved in condition, the two fragments of liver united perfectly, the cauterized surface healed speedily, granulations sprang up rapidly in the muscular tissue and continued until the divided muscles were reunited and integument formed over the entire surface. The case terminated in complete recovery in about seventy days.

GASTROTOMY FOR INTESTINAL OCCLUSION.—Dr. Samuel Whitall, in an interesting and elaborate paper on the above subject, gives a history of the operation from the earliest days down to the present time, and discusses at length its feasibility, the modes of its performance, the objections which are urged against it, and the beneficial results which are to be hoped for from it.

He details, classifies, and tabulates thirty cases of operation, and finds that when the conditions were as favorable as one could reasonably expect in a disease of such great fatality—*i.e.*, when there existed no serious abdominal obstacle, such as extensive peritonitis, gangrene, perforation, insuperable occlusion, etc.—"one hundred per cent. were saved, whereas without such interference every one of these must unquestionably have died."

He says the term *gastrotomy* is an unfortunate one, and had better be restricted to the operation of opening the stomach, *laparotomy* more accurately expressing simple abdominal section. "The term *gastrotomy* (or

laparotomy) in its present connection is applied to a large incision made through the abdominal walls for the purpose of searching for, and, if possible, of relieving, internal intestinal obstruction. If after laying open the abdominal cavity the operator should open the intestine, whether he intend to sew it up again and return it into the peritoneal cavity, or to establish an artificial anus, the operation receives the name of *gastro-enterotomy*. *Enterotomy* is applied to the operation which has for its object the establishment of an artificial anus, whatever may be the process employed or the seat of the operation."

In reply to the query, What can be accomplished by the operation? he answers—1. The restoration of the patient to perfect health by the complete removal of the obstruction without opening the intestinal canal.

2. In cases of intramural occlusion, it enables the operator to discover its exact locality, and after having removed the obstacle he can sew up the bowel and return it into the abdominal cavity, or establish an artificial anus, as circumstances require.

3. Should the seat of the obstruction not be discovered, it enables the surgeon to form an artificial anus as near as possible to the affected point, in the hope that, the intestinal tension being thus relieved, the passage would become clear and the artificial opening subsequently close.

4. The seat of the obstruction being recognized but found to be insuperable, it enables the operator, by the formation of an artificial anus, greatly to relieve the patient's sufferings, in mitigating the pangs of unavoidable death.

This paper was written by Dr. Whitall apropos of the death of Dr. Tyce, of New York City, in whose case he believes gastrotomy would not only have been justifiable, but would have been of incalculable benefit.—*New York Medical Journal*, August, 1873.

ITCH IN THE LEOPARD.—Dr. Theodor Simon, of Hamburg, records, in the *Archiv für Dermatologie und Syphilis*, No. 1, 1873, a case of scabies in the leopard, which came under his notice. The animal was an old member of the Zoological Garden collection, and crusts upon various parts of his body had been noticed for some time previous. The leopard was examined and some of the crusts were taken from his head, and under the microscope showed epidermic scales, blood-corpuscles, and numerous itch-mites, together with their excrement and eggs. The insects were found to be of all ages, and both males and females were discovered, though the latter were greatly in excess. Upon close study, the mites were determined to be identical with the human itch-mite, or *Sarcoptes hominis*. The disease was most marked about the head and breast of the animal. In what way the scabies had been contracted could not be discovered, for the keeper in charge of the leopard, although frequently touching him, was free from any trouble of the kind. The beast was successfully cured by inunctions of balsam of Peru, which were made, not without difficulty, by the keeper. Some time after, the leopard died suddenly, and the examination of the body showed no trace of the former scabies.

ACUTE ANÆMIA DUE TO FRIGHT.—An interesting case presented itself at St. Bartholomew's Hospital, in the person of a young woman, æt. 20, pallid, bleached, not menstruating, and with the typical aspect of an anæmic female. She stated that ten weeks previously she was in perfect health, had a good color, and menstruated regularly. At that time a fire had broken out in a house adjoining that in which she lived, and she had been exceedingly alarmed. Since then her menses had ceased and she had assumed her present appearance.

There can be no doubt that anæmia is too frequently regarded and treated as the result of a constant blood-defect—the consequence of a chemically altered circulating fluid. Such cases direct attention to a deeper and more significant pathogeny for some forms of anæmia,—an altered condition of the nervous system. *British Medical Journal*, Aug. 23, 1873.

ATROPIA IN CHOLERA.—During a recent outbreak of cholera, Dr. R. Saunders obtained excellent results by the hypodermic injection of one-fiftieth to one-thirtieth of a grain of sulphate of atropia. In some cases the relief afforded was astonishing: the more distressing symptoms—vomiting, purging, and cramps—were ameliorated almost at once; the skin grew warm, the pulse rose, the surface, previously clammy and shrivelled, assumed its natural condition, and in some instances the patient slept soundly for ten or twelve hours, the bowels remaining undisturbed during the entire time. These effects, however, only followed when the atropia was used in sufficient quantities to produce the specific scarlatina rash, dry throat, and dilatation of the pupils.—*The American Practitioner*, July, 1873.

MORPHIA IN ACUTE URÆMIA.—Dr. Alfred Loomis asserts that morphia can be administered hypodermically to some, if not to all, patients with acute uræmia, its almost uniform effects being—1, to arrest muscular spasms by counteracting the effect of the uræmic poison on the nerve-centres; 2, to establish profuse diaphoresis; 3, to facilitate the action of cathartics and diuretics, especially the diuretic action of digitalis. It must be given in sufficient quantities to control convulsions, as neither the contraction of the pupils nor the number of respirations is a reliable guide in its administration.—*New York Medical Record*.

MISCELLANY.

CULTIVATION OF IPECACUANHA.—Dr. G. Henderson, in his report on the Royal Botanical Gardens, Calcutta, published in the *Calcutta Gazette* of June 25, describes the progress which has been made in the cultivation of ipecacuanha. There are now about seven thousand plants either at Rungbee or Calcutta, and no difficulty appears to exist in propagating the plant artificially. The conditions under which it will flourish in the open air have not been as yet determined. Experiments are, however, being made in this direction. Dr. Henderson has also tried to cultivate the *Exogonium purga*, which yields the jalap of commerce, but as yet without success.—*Indian Medical Gazette*.

DR. M. DE CHRISTOFORIS and Dr. Zambelletti, of Milan, announce that their proposal for the study and initiation of a universal pharmacopœia has been accepted by the Executive Committee of the Viennese Medical Conference, and will be brought into public discussion.—*Medical and Surgical Reporter*.

STREET-ACCIDENTS IN LONDON.—These injuries, of which only 1334 were reported in 1866, increased steadily to 1919 in 1870, leaped up to 2445 in 1871, and were 2677 in 1872. Altogether, since 1866 there have been 771 persons killed in the streets and 12,630 persons more or less injured.

CHOLERA.—According to official reports, there have been of deaths from this disease in—

Cincinnati, August 16 to 30,	11
Elmira, N.Y., for August,	1
Evansville, Ind., for four weeks ending August 24,	9
Indianapolis, for August,	40
Louisville, for week ending August 23,	2
St. Louis, for week ending August 23,	9
Wheeling, for August	4

The Sanitarian.

HOW TO SWALLOW A PILL.—*The Chicago Medical Times* is responsible for the following: "Put the pill under the tongue and behind the teeth, and let the patient immediately take a large swallow of water, and he will neither feel the pill nor taste it. In fact, he cannot tell where it has gone; and I have seen them (*sic*) look about the floor to see if they had not dropped it."

THE International Congress of Physicians at Vienna was opened on the 1st of September, by the Archduke Rainer. The subject of vaccination was the first question presented for discussion. In our next number we shall give to our readers, through our own correspondent, an account of its proceedings.

A SOLUTION of five parts of borax in one hundred of water is represented to prevent the putrefactive process in meats for considerable time. Flesh dipped in the mixture and then dried resists the usual process of decomposition.—*The Sanitarian.*

THE death of two members of one family, and the dangerous illness of the remainder, four in number, from drinking the milk of a goat which had eaten *Aethusa cynapium*, are reported to have occurred in the county of Limerick.

MR. JOHN STUART MILL has bequeathed £3000 to any one university in Great Britain or Ireland that shall be the first to open its degrees to women, and to the same university a further sum of £3000 to endow scholarships for female students exclusively.

THE Russian lady medical students have been refused permission to study medicine at the Universities of Strasburg and Giessen by the authorities of those institutions.

LIDIA RODELRENA, a wealthy Russian lady, has just presented to the St. Petersburg Academy of Medicine \$40,000 to endow a department for the medical instruction of women.—*Western Lancet.*

A REAL lover of his race, in view of the approaching era of political speech-making, advertises for some secret and expeditious method of communicating lockjaw.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM SEPTEMBER 23, 1873, TO SEPTEMBER 29, 1873, INCLUSIVE.

BAILY, E. J., SURGEON.—When relieved by Surgeon Magruder, to proceed to Wilmington, Delaware, and report by letter, upon his arrival there, to the Surgeon-General. S. O. 187, c. s., A. G. O.

McPARLIN, T. A., SURGEON.—When relieved by Surgeon Irwin, to report in person to the Commanding General, Department of the Missouri, for assignment to duty. S. O. 187, c. s., A. G. O.

MAGRUDER, D. L., SURGEON.—When relieved by Surgeon Alexander, to report in person to the Commanding Officer, Department of Arizona, for duty as Medical Director. S. O. 187, c. s., A. G. O.

PAGE, CHARLES, SURGEON.—Relieved from duty at Fort D. A. Russell, Wyoming Territory, and assigned to duty at Omaha Barracks, Nebraska. S. O. 140, Department of the Platte, September 12, 1873.

RANDOLPH, JOHN F., SURGEON.—Relieved from duty at Omaha Barracks, Nebraska, and assigned to duty at Fort D. A. Russell, Wyoming Territory. S. O. 140, c. s., Department of the Platte.

IRWIN, B. J. D., SURGEON.—To report in person to the Superintendent of the Military Academy, West Point, New York, for duty. S. O. 187, c. s., A. G. O.

ALEXANDER, C. T., SURGEON.—Assigned to duty as Attending Surgeon at St. Louis, Missouri. S. O. 187, c. s., A. G. O.

WEEDS, JAMES F., SURGEON.—Granted leave of absence for thirty days, on Surgeon's Certificate of Disability. S. O. 204, Department of Dakota, September 12, 1873.

WOLVERTON, W. D., ASSISTANT-SURGEON.—Granted leave of absence for thirty days. S. O. 186, c. s., A. G. O.

BROWN, HARVEY E., ASSISTANT-SURGEON.—Assigned to duty at Key West, Florida, as soon as his services can be dispensed with at Fort Jefferson, Florida. S. O. 148, Department of the Gulf, September 12, 1873.

RETURN OF DEATHS AND INTERMENTS IN PHILADELPHIA FROM AUGUST 30 TO SEPTEMBER 27, 1873.

SATURDAY, OCTOBER 11, 1873.

ORIGINAL COMMUNICATIONS.

APHONIA.

BY ANDREW H. SMITH, M.D.,

Surgeon to the Throat Department of the Manhattan Eye and Ear Hospital, N.Y.

(Concluded from page 3.)

THE treatment of unilateral paralysis depends upon the cause. When from disease of the brain, no treatment is likely to be of any avail. When caused by toxæmia, in addition to general treatment adapted to the condition of the system, good effects may sometimes be obtained by direct electrization. In Mackenzie's electrode for this purpose the poles are connected with two olive-shaped points separated from each other about a quarter of an inch. This instrument is brought as near as may be into contact with the affected muscle, when, by pressing a key, the current is made to pass from one point to the other of the electrode through the intervening tissue. This has been found more successful than when one of the poles is applied outside of the neck.

In some of these cases, irremediable changes having taken place in the muscles themselves, no treatment will be of any service. In general the prognosis is favorable in proportion as the case is recent, chiefly for the reason that, there being no action whatever of the muscles, atrophy is almost certain to take place in the end.

Bilateral paralysis of the adductors is rarely the result of interference with the laryngeal nerves by causes of organic origin. It may, however, be caused by disease of the medulla affecting both lateral tracts.

But in by far the greater number of cases it is purely functional, if this term is ever allowable, and the resulting aphonia is called functional aphonia.

In this disease there is no apparent change of structure either in the larynx or in the nerves which supply its muscles. There is simply a paralysis of one or more of the muscles, which has no appreciable anatomical change to account for it. From its frequent association with hysteria, it is often called hysterical aphonia. Yet it is by no means confined to this class of patients. Its pathology is very obscure. The muscles are intact, the nerves are perfectly competent to transmit the nervous influence from the brain, and the brain is perfectly competent to originate the influence. Still the patient is utterly unable to bring the muscles into action until the spell is dissolved either spontaneously or by some external agency, when all at once the parts resume their natural function.

This form of aphonia is apt to come on suddenly, as the result of fright, anger, or other emotional excitement, or even without any apparent cause. Very often it will occur during the menstrual period, and sometimes for months together each return of the catamenia is regularly accompanied by loss of

voice. This intimate connection between the uterus and the larynx is shown also by the fact that some female singers are obliged to make their public engagements in a way to exclude the menstrual periods, as at that time they are unable to sound the higher notes.

The voice has always a whispered character, but its loudness varies in different cases, and at different times in the same case. Sometimes the voice is almost wholly suppressed, at others there is a loud whisper which may be heard the length of a large room.

The reflex action of the cords is but little impaired, and, as a consequence, coughing and sneezing are distinctly laryngeal. This is a diagnostic point of great value. In many cases the lips seem to be partly paralyzed and do not exhibit their natural play in speaking. With the return of the voice the usual mobility is restored.

The laryngoscopic appearances in this disease vary according to the muscles affected, but are comprised chiefly in four varieties.

In the first *all* the muscles of phonation are paralyzed, and when phonation is attempted the cords remain perfectly motionless. The glottis is widely open and has a triangular form.

In the second there is paralysis of the lateral crico-arytenoids. On attempting to pronounce a vowel sound the arytenoid cartilages are drawn towards each other by the arytenoideus, but they do not rotate; and hence the glottis assumes a lozenge shape.

In the third form the arytenoideus proprius is paralyzed. When phonation is attempted, the arytenoid cartilages rotate and the ligamentous portion of the glottis is closed, but a triangular opening is left posteriorly.

In the fourth variety there is paralysis of the thyro-arytenoids. The posterior third of the glottis is closed, but an elliptical opening remains between the ligamentous cords.

This affection will generally terminate in recovery after a variable time, even if left to itself. And in this case the voice comes back as suddenly as it left. On attempting to speak, the patient is surprised to find that instead of a whisper there is a full laryngeal tone, though the voice may still be hoarse.

Although the voice generally returns of itself, the aphonia is sometimes very persistent. Mackenzie mentions a case which he cured after it had continued ten years. And in a case of my own, published in the *New York Medical Journal*, April, 1873, the duration was six years and a half. Yet there is scarcely any other affection of the larynx in which treatment is so certainly and, as a rule, so promptly successful.

Almost any application to the larynx which creates considerable spasmodic action may be successful,—immediately restoring the voice. Sometimes the mere introduction of an instrument into the throat, as, for instance, the laryngeal mirror, will produce this effect, provided the patient be impressed with the idea that it is expected to do so. The inhalation of ether or chloroform to the stage of excite-

ment will generally set the patient to talking, and the voice will remain after the effect of the anæsthetic has passed off.

But by far the readiest means is the application of electricity directly to the cords. The best instrument for this purpose is Mackenzie's laryngeal electrode. This consists of a simple metallic staff, bent at the proper angle, and covered, except at the point, with some insulating material. An eye in the handle is connected with one of the wires of the battery, and by depressing a trigger attached to the handle is made to communicate with the staff when the point of the latter is in position. The other pole may be held in the hand or placed upon the throat over the larynx.

As a general rule, cases of not more than a few weeks' standing may be relieved in this way at the first sitting. Cases of longer duration sometimes require several sittings, or even perhaps weeks of treatment, to entirely restore the voice.* It is well to repeat the application two or three times on each occasion, and not to allow more than two or three days' interval between the sittings.

The daily application of electricity to the throat, externally, for a week or two after the voice is restored, is useful to prevent relapse, to which there is a strong tendency.

Though functional aphonia is most frequently seen in women, and during the period between puberty and the menopause, I have seen several cases in which it occurred in men.

It frequently follows upon congestion of the larynx from cold, in which case the aphonia is at first organic, but remains as a purely functional disease after the congestion has disappeared.

During the spring of 1862 I had a soldier under my care who had taken a severe cold from standing on guard in a drenching rain. The cold affected the throat, producing hoarseness, which soon passed into complete aphonia. A few days of treatment relieved the inflammatory symptoms, but the aphonia persisted for three or four weeks. At length, as an experiment, I introduced into the throat a probang loaded with tincture of iodine, which produced a good deal of coughing and spasm. After the application he returned to his tent, and in a few minutes, having occasion to speak to one of his comrades, he found that his voice had fully returned. From that time forward he had no further difficulty.

An acquaintance of mine, also in the army, became aphonic from a similar cause, and remained without his voice for a period of eighteen months, when it returned suddenly and perfectly, of its own accord. Doubtless, had electricity been applied in the outset, at least seventeen of the eighteen months of aphonia might have been spared him.

Another case now under my care illustrates in a marked way many of the peculiar features of functional aphonia.

Mrs. C., aged about 34, married eleven years, but

has no children, is of a highly nervous organization, but yet a person of strong mind and unusual self-control, in everything directly the opposite of what is generally termed *hysterical*. Has no other symptoms of uterine disease than somewhat profuse menstruation, and sterility. For the last two years has had a tender spot between the scapulæ, with the usual attendant symptoms, constituting a typical case of spinal irritation.

Two years ago she took a severe cold, followed by a distressing cough, sore throat, hoarseness, and finally aphonia. The sore throat and aphonia persisted for two or three weeks after the severity of the cough had passed. The voice then came back suddenly, but after two weeks was again lost, and remained absent for a fortnight. This state of things continued some eight months, the voice being present and absent alternately for from two to four weeks at a time, the general health meantime continuing in a most unsatisfactory condition, notwithstanding the use of every means to build up the nervous system. The attacks of aphonia occurred with great regularity with each menstrual period, and occasionally in the intervals. When the voice returned it was generally suddenly, without any apparent cause. During all this time stimulating applications were frequently made to the larynx during the aphonia, with the hope of restoring the voice, and electricity to the outside of the throat was thoroughly tried, but all to no purpose. Electricity directly to the cord was tried on one occasion, but was unsuccessful, and excited so much opposition on the part of the patient that its further use was deferred. About eight months, however, after the first attack, it was again tried, and was successful at the first sitting, as it has been on every occasion since. From November, 1871, to the present time, the patient has never retained her voice longer than three weeks, and has lost it on an average every ten or twelve days. She has a battery and a laryngeal electrode at her house, and as soon as her voice is lost she sends for me to restore it. A singular point is that while the voice is absent all her other symptoms are greatly aggravated. She especially suffers from a sense of weight and oppression about the upper part of the sternum,—a form of *globus hystericus*, I presume,—which is immediately relieved when the voice is restored. That the loss of voice is not the result of a hysterical access of which this *globus* forms a part is shown by the fact that the aphonia generally comes on first, and that with its removal the sense of oppression in the chest is also removed.

The return of the voice, whether spontaneous, as it still sometimes is, or artificially induced, is always preceded by a peculiar sensation in the throat, which the patient describes as a "breaking away of something." She always knows that she can speak before she makes the attempt.

The attacks of aphonia are almost always consequent upon some unusual exertion. Attendance at church, for instance, is nearly certain to entail loss of the voice before the day is over. A singular circumstance is that three times out of five the voice disappears while at the dinner-table.

* In my case before referred to, in which the aphonia had existed for six years and a half, the treatment was continued for six weeks before the voice was fully restored. There was a complication of lead-poisoning, however, affecting the arytenoides, an earlier recognition of which would have materially shortened the treatment.

At one time I procured for her a galvanic neck-lace, as recommended by Gibb, and it certainly did benefit her for a time, the attacks being much less frequent; but it soon lost its effect.

Sometimes in these cases of functional aphonia the voice may be restored by a strong mental impression. A striking instance of this occurred in a patient, a young girl, whom I saw some thirteen years ago in a small town near Philadelphia. She had curvature of the spine, and in addition to this there had been an abscess somewhere near one of the kidneys, which discharged through the vagina, leaving a suppurating cavity from which there was a constant drain of pus. She was paraplegic and aphonic, with marked hysterical symptoms. Shortly after I saw her, the notorious miracle-worker Newton came to the town, and, being told of the case, went to the house, and, entering suddenly into the room, fell upon his knees near the door, and prayed in a most impressive manner that the Almighty would give him power to relieve the sufferer. He then advanced to the bedside, and, taking the girl by the hand, said, with great earnestness and solemnity, "My child, you can speak: tell me your name." This she did immediately, and from that time forward retained her voice.

I have purposely left what few remarks I have to make upon the pathology of functional aphonia until after relating the above cases, for the reason that they illustrate a distinction which I think important, and which, so far as I know, has not heretofore been made.

It appears to me that as to its pathology functional aphonia is divisible into two forms, in one of which there is, to use the words of Dr. Cohen, "a defect of innervation at the points of ultimate distribution" of the nerves, and in the other a defect of the will. With the first I would class such cases as follow upon organic troubles in the larynx, and such others as are plainly reflex in their origin. In these cases local treatment is not so promptly efficient as in hysterical cases, but it almost always succeeds in the end. Mental impressions, as they are not an exciting cause of the aphonia, are powerless to restore the voice.

In this form the voice when first restored is usually weak and hoarse, but it improves with use and soon regains its normal tone.

In the second or hysterical form the fault is in a defect of the will, of which the patient is unconscious. She thinks she is making a bona-fide effort to speak, but in reality no motor impulse is originated in the brain. But let her be impressed with a belief that she can speak, or with an overwhelming desire to speak, and the power to do so is found to be present. Now, if there were a condition of the nerve at its distal extremity which unfitted it for transmitting a motor impulse, it is clear that no cause acting proximally could produce any effect. It is in these cases that strong mental impressions sometimes effect a cure, as in the case last narrated. The simple introduction into the fauces of any indifferent instrument, as, for example, a laryngeal mirror, with the assurance that it is designed to recall the voice, will often prove effectual, while the same manipulation without such assurance would pro-

duce no effect. The condition is precisely analogous to that in hysterical paralysis generally, which, we all know, can be overcome whenever a sufficient motive for action is presented.

It is in this class of cases that the inhalation of chloroform often restores the voice. It acts simply by causing the patient to forget the idea that she cannot speak, when the natural inclination to talk obtains the ascendancy.

The restoration of the voice is usually complete from the first,—the first word uttered having a clear and natural tone.

At first sight it appears strange that in functional aphonia the muscles of phonation do not become atrophied by years of inaction. But this is explained by the fact that the reflex actions of sneezing, coughing, etc., and also the movements of the glottis which accompany respiration, still continue, and constitute sufficient exercise for the muscles to prevent atrophy, forming a contrast in this respect with what takes place in unilateral paralysis, where all motion of the affected muscles is usually suspended.

Paralysis of the crico-thyroid muscles, while it usually results in dysphonia only, occasionally causes complete loss of voice. This affection is most commonly the result of over-straining the voice, particularly in the higher notes. It is characterized by relaxation of the vocal cords, which, when the case is well marked, are seen by the aid of the laryngoscope to be swayed by the passing current of air in inspiration and expiration, bellying downward and upward. The free margin of the cord is often wavy instead of straight.

The treatment consists in absolute rest—that is, absolute silence—for a time, and the use of electricity. As the crico-thyroid muscles lie in front of the larynx, covered only by a thin layer of soft parts, it is easy to reach them with the electric current by applying the poles externally. There is an advantage, however, in introducing one of the poles into the larynx in contact with the inner surface of the thyroid cartilage, as the current is then compelled to pass more directly through the muscles. The cure cannot be expected to take place as speedily as is generally the case in paralysis of the adductors.

THE THIRD INTERNATIONAL MEDICAL CONGRESS.*

HELD AT VIENNA, AUSTRIA.

Reported by FREDERICK W. RUSSELL, M.D.

THE first gathering of the Congress occurred Sunday evening, August 31, when such delegates as were in the city, with their wives and lady friends, assembled in the pleasant dining-room of the Grand Hotel and dined together in a social and informal way. Companies of friends gathered at the various tables and passed several hours in social

* In order to have our report of the Viennese Medical Congress as fresh as possible, we have allowed it to displace in our present issue the clinical lecture and the notes of hospital practice.—ED. MEDICAL TIMES.

enjoyment, while old friendships were renewed and new ones formed.

The first regular meeting of the Third International Medical Congress took place on Monday, September 1, at ten o'clock A.M., in the main saloon of the Jury Pavilion, on the square in front of the Rotunda. Before the appointed hour, some five hundred delegates and members, both civil and military, had assembled, coming from all parts of Europe, and a few from the Western continent. The officers of the day received at the entrance the Archduke Rainer, a tall gentleman with close-cropped gray hair and a handsome blonde moustache, and escorted him, as Patron of the Congress, within the place of meeting. Delaying for a few moments while he exchanged a few pleasant words with such of the delegates as were presented, he then mounted the rostrum, and, with Prof. Rokitsky, Prof. Hebra, Prof. Sigmund, Dr. Schnitzler, and Prof. Benedict on his right and left, read a short address, formally opening the deliberations of the week. In substance he said that it gave him pleasure to welcome the delegates to the capital of Austria, the site of the *Weltausstellung*. The Exposition would be incomplete if it brought only the results thus far obtained, though it has planted a germ for future growth. The questions which the prominent physicians of the world are striving to answer are truly international, having in view the well-being of all. Though they heal the sick, the most pressing question of the time is the *preservation* of health, the prevention of disease. Civilization brings upon great centres of population great evils and perils, which make the warding off of disease of paramount importance. A new point of view becomes necessary, a new mode of action for combating the evils which threaten mankind. "As you have brought forward these matters and fixed attention upon them, it is your privilege and duty above all others to find and provide help. You will merit new honor from mankind, and add a new glory, and that the best of all, to the World's Fair."

Prof. RATTI, of Rome, delegate from the Italian government, replied, in behalf of his confrères, that the Congress ought to be successful, since it is called to examine into measures which are to conduce to the public welfare and to shape them uniformly for all states. He was strongly of the opinion that a single wise effort on the part of the leaders could establish an international system of public hygiene, pregnant with happiness and prosperity to all generations.

Prof. CARL ROKITSKY, President of the Congress, then rose, and read an address in which he said that it was an honorable task to open these deliberations. He could aim at nothing more than advice concerning the significance of our meetings, and to bring into view the prominent ideas which all had in mind,—in fact, give a roll-call of the work before us. With courteous expressions of regard and hospitality he continued, remarking that associations for hostile purposes, especially of tradesmen to resist oppression, had existed from primitive times. If medical men had long seen the enemy and his devastations before they were induced to

oppose it, it must be observed that it takes generations to lay the foundations for the union of personal efforts, and that organic and inorganic nature must be first investigated in order to understand the foe, to search out its breeding-places, its peculiarities of attack, and its destructive effects. The word international has been adopted because interests of the utmost importance to the people were to be discussed. The people are being convinced that only through united action, both in theory and practice, can the longed-for benefits be obtained. The greater the value of the good sought, the more weighty the deliberations of the Congress. A great value is necessarily given to our discussions, because the press will scatter them far and wide, and each speaker thus reaches a larger audience. He wished not alone those students and writers upon these special subjects to give their opinions, but all to bring forward whatever of experience, of established fact, might be in their possession. We need to find out the whole natural history of the disease, in order to properly manage it. No longer do the people regard these things as sent by an angry Deity; they turn for advice and aid to the physician. And he is at his post, here and there, in hand-to-hand conflict at the bedside, or as a soldier in the war of extermination against the hostility of the foe. We must win the confidence of the people, and induce governments to establish regulations, that the advent of the enemy may not find us unforewarned and unprepared.

Dr. J. SCHNITZLER, the General Secretary, then made an earnest speech, explanatory and historical, read the list of delegates, the permanent officers, and officers of sections, and at an early hour the President declared the session closed.

Officers of the Congress:

His Highness the Archduke Rainer, *Protector*.

Prof. Dr. Carl Rokitsky, *President*.

Docent Dr. Joh. Schnitzler, *General Secretary*.

Prof. Ferd. Hebra, Prof. Sigmund, Prof. M. Benedict, *Vice-Presidents*.

The Executive Committee consists of nineteen members, delegates from the various medical societies of Vienna, embracing such men as Profs. Arlt, Billroth, Braun, Brücke, Schroff, Drs. Witlacil, Winternitz, Auspitz, and Profs. Meynert, Stricker, and Späth. Among the delegates I find the names of Eulenberg of Berlin, Jaccoud of Paris, Profs. Crocq and Warlomont of Brussels, Dr. Günther of Dresden, Prof. Subbotin of Vienna, Prof. Carminhoe of Brazil, Dr. Kovacs of Pesth, Dr. Abdullah Bey of Turkey, and Dr. Castiglione of Rome. But one English physician has thus far registered, and America has almost no representation.

During the sessions of the Congress the following questions are to be discussed in order:

1. The question of vaccination.
2. The proposition of an international law for the prevention of syphilis and the regulation of prostitution.
3. The question of quarantine measures against cholera.
4. The drainage of cities.
5. The proposition for the adoption of an international Pharmacopœia.

6. The proposition for making medical studies uniform, and, as a result, the right of practising the art freely in any country.

Each question is assigned to a president and a committee, who have the position of experts, to outline the subject for discussion, and to formulate the sentiments of the Congress for the ballot. These are printed and distributed before each session, as well as a daily bulletin containing the proceedings of the previous day.

FIRST SESSION.

The first session of the Congress began on Monday afternoon, at four o'clock P.M., in the same saloon, which, owing to the constant squeaking of the bent-wood chairs, and the rather uncalled-for confusion, was not perfectly suited to the purpose. Prof. JACCOUD, of Paris, acted as President, assisted by Prof. HEBRA, of Vienna, and Prof. CASTIGLIONE, of Rome, while, with HEBRA as chairman, Drs. KAPOSI and AUSPITZ formed the committee to whom the general subject had been referred. The question under discussion was vaccination, and the committee circulated a printed brochure containing ten questions, and suggestive remarks, of which the following is a summary:

Question 1. "Shall vaccination be universal, and, if so, shall it be with humanized or original cow-pox virus? How is this to be obtained and kept?" The committee remark that all impartial observations prove that, in respect of frequency, intensity, and mortality, vaccination furnishes an actual if not absolute protection, and that smallpox shows the same virulence towards the non-protected as it did of yore. Secondly, that every non-vaccinated person becomes a source of contagion for others, and multiplies the common danger, and also that no principle is sounder than that the state can protect itself against individuals. Therefore the referees advise *compulsory universal vaccination*. Again, the original lymph takes less certainly, and more often develops a more intense local action, which may be the source of dangerous, even fatal, processes; while humanized lymph can be easily and cheaply obtained in large quantity, less often fails, and rarely develops any unseasonable complications. It were best, then, as a rule, and in all official vaccination, to *use the humanized lymph*. Some persons, however, fear the possible introduction of germs of disease in this way; and in all cases, without further ado, it is best to satisfy their wishes. Next they remark that *the lymph is to be obtained by an incision permitting free escape without pressure, made in a perfected pustule in its prime, when its contents are perfectly clear and limpid, midway between the eighth and tenth days of the eruption*, and only such lymph should be used as comes out spontaneously in clear drops. Lastly, the more immediate the use made of the virus obtained, the more perfect the results. Therefore its reception in a special vial is unequivocally recommended. But generally some days must elapse before it can be used; and, to obviate in some degree this objection, three preservative measures are in use. 1. Simply *drawing it into capillary vials*, which, the committee say, if well done, carefully

sealed, and kept in a cool place, would *preserve the lymph admirably*. 2. *Drying the lymph on the point of the lancet*, a method which preserves for a long time the working power of the lymph, but is *not, on the whole, so advisable*. 3. The method of *suspension of the lymph in glycerin*, a method extensively tried of late, which *offers all the advantages of the first, with great economy of the lymph*.

Question 2. When ought vaccination to be undertaken? At any time of the year, or at a definite time? The committee reply, *time and weather have no counterindication*.

Question 3. What age is the best for vaccination? Provided a child is not in a condition of fever, *it should be attended to as soon as possible*. A child four or five days old can undergo the development of the pustules without marked physical disturbance, and when peculiarly exposed (children of physicians) should be vaccinated *at once*.

Question 4. (a.) What protection does vaccination afford against variola? (b.) How many years does it last? (c.) What is the number of cases of variola among the protected and the non-protected? (d.) How do the statistics of mortality in both classes compare, as determined by the experience of the last decade? The committee confess great difficulty in answering these questions in formal statements. Yet experiment, statistics, and general clinical experience agree that vaccinated persons are less accessible to the smallpox than non-protected individuals. The protection seems to extend over twenty years. Proof is found in the increase of cases of from fifteen to thirty years of age, and the possibility of a second vaccination taking; though it is to be noticed that a small proportion of the cases occurring in those over thirty years old are in non-vaccinated persons. But again, more people are alive between twelve and thirty than from thirty to ninety. Certain it is that many persons preserve to old age their immunity against variola and vaccinia. As regards the number of cases of smallpox in the two classes, it is impossible to clearly state the proportions, owing to imperfection of reports. The greater absolutely the number of vaccinated, the greater relatively will be their share of cases. Wherever the number of living vaccinated persons is known, it must be admitted that fewer of that class have had variola than of the non-vaccinated. Beyond a doubt the mortality among the vaccinated is less than among those not vaccinated. Mortality varies empirically among the protected from 0 per cent. to 11.5 per cent., with average of 4 per cent.; among the non-protected it ranges from 14.5 per cent. to 60.6 per cent., average 30 per cent.

Question 5. Is variola found so frequently in individuals with large and deep vaccination-scars, as in those with small, flat, and obscure cicatrices? No evidence exists on this subject, and, therefore, conclusions are impossible.

Question 6. Is there information to prove that, through vaccination with vaccine lymph, diseases previously non-existing, as tuberculosis, scrofulosis, and rachitis, have been introduced? On this the committee reply that, although the transmissibility

of all known diseases is as yet to be learned, its transmission by vaccination has as yet been proved by no one.

Question 7. Can an existing disease, syphilis for example, be transferred to a healthy subject through vaccination with vaccine lymph from children suffering with hereditary syphilis? Or has every development of a syphilitic pustule arisen from inoculation with fluid taken from a syphilitic eruption? Transmission of syphilis has occurred, beyond a doubt; but the danger is nil if only pure lymph, from a pustule in a person who has no manifest syphilitic taint, is used. Again, it is only when blood or the pus of syphilitic suppuration has been used in the vaccinating that such transmission is possible. Such diagnostic error is easily avoided by any careful physician who is acquainted with the known clinical symptoms of syphilis.

Question 8. Is answered that there are characteristic and, in a clinical sense, important appearances by which syphilis can always be distinguished.

Question 9. (a.) How is the frequently observed imperfect inoculation of vaccine to be explained? At present we cannot explain it; but it has an analogue in the non-susceptibility of certain individuals to prevailing disease. *(b.)* Are we to think a long continuous use of the same lymph brings these conditions into existence? And would it therefore be wise now and then to recommend re-generation of the lymph through cow-pox lymph? Although as facts now stand we cannot affirm a degeneration of power and quality, yet an occasional return to the original lymph would be advisable, in order to obtain better humanized lymph and to allay fear of contagion from the use of a long series of perhaps unhealthy persons.

Question 10. What diseases do we see attacking the vaccinated, which have the same course and issue? Such as follow any other specific irritation of the skin: erythema simplex et bullosam, eczema, lymphangitis, erysipelas, and adenitis suppurativa. But all are rare, and easily avoided by care and the use of pure lymph.

In addition to these questions, information was asked whether there is only one contagion for severe and light cases of variola, *i.e.*, vera, modificata, and varicella, or is each a species of variola, or do variola and varicella only come into existence through a special specific contagion? As regards this question, two of the referees (Hebra and Kaposi) have often announced their belief in the identity of the two, while Auspitz thinks that the experimental data do not allow of a definite answer.

After a few words from the President, Prof. JACCOUD, Prof. HEBRA addressed the meeting, saying, after a few eloquent words of introduction, that the chief duty of a Congress was to make universal whatever of discovery each physician had made. Learned discussion of theoretical points was not wanted, but rather the promulgation of the results of observation made from the proper objective point of view. From these the propositions can be formulated which will conduce to the life and happiness of mankind. Guided by such principles, the discussion will not be barren, and we shall be prepared

either to strongly endorse vaccination, or, if the majority shall decide that it has no protective influence, we shall also be ready not to conceal these views. He particularly wished the question of the identity or non-identity of variola and varicella to be freely discussed, and facts to be fearlessly brought forward: both sides should be treated with like impartiality.

Dr. KAPOSI then read the brochure before mentioned, and a vigorous discussion began. Dr. REITZ, of St. Petersburg, declared himself *opposed* to vaccination, as a result of clinical observations made at the Elizabeth Children's Hospital. From March 9, 1870, to January 1, 1873, he investigated 18,786 children, and found in 8326 vaccinated 133 cases of smallpox, or 1.6 per cent.; and in 10,460 non-vaccinated only 215 cases, or 2 per cent., a most insignificant variation. This, too, at a time of life when the disease is especially frequent. Comparing similar hospital material at Berlin, Vienna, and Brester, of 820 sick vaccinated and revaccinated patients during 1871, 256 died, or 31.2 per cent.; while of 86 not protected, only 23 died, or 26.7 per cent. Again, in the Berlin epidemic of 1871, vaccinated children were affected to a remarkable extent, and the mortality attained the "colossal" figure of 55.3 per cent. The dangers of vaccination he believed understated, since blood-corpuscles are found in the clearest lymph. He introduced a resolution postponing any decision until the next Congress, owing to lack of exact statistics, and requesting such information.

Prof. WARLOMONT, of Brussels, declared vaccination to be indispensable, and that he was a friend of animal lymph, because that offered an inexhaustible source of material, ready at a moment's warning to meet any demand, and because also it offered stronger protection against the inoculation of syphilis. In closing, he said that up to this time the comparative study of humanized and animal lymph did not enable us to decide which of the two is best.

Dr. HERRMANN, of Pesth, was an opponent of vaccination, saying that Jenner in 1799 declared the practice a protection against all kinds of contagion,—an error now exploded. Its friends to-day say that it has reduced the amount of smallpox. From 1776 to 1800, 7017 cases were treated in the London Hospital; from 1801 to 1835, the practice being in vogue, only 3743; in the Vienna General Hospital from 1836 to 1861 there were 8483, and from 1861 to 1863 there were 2162, of which 1300 were in 1862. Also some years of comparative exemption occur, wholly without regard to vaccination. Again, they say that the vaccinated are protected. In the Vienna hospital from 1836 to 1856 there were 6213 cases, of which 5217 were vaccinated, while Gregory had from 1836 to 1851 a proportion of 3.1 vaccinated to 2.7 non-vaccinated. Hebra explains these unfavorable reports by saying that, of 1323 sick with variola vera, 591, or 59 per cent., were unvaccinated, while 732, or 41 per cent., were vaccinated. As regards the assertion that the mortality had been reduced, the speaker said that it must be acknowledged that its protection

lasted for only a few years. To enumerate those sick with the disease ten years after vaccination was a wholly false plan, since this, as other diseases, selects certain ages within which to work. In London since 1858 statistics show a vast preponderance of deaths from variola before the age of ten years, while only 2.4 per cent. occurred from 55 to 65 years. If now the protection was lessened by lapse of years, one would expect exactly contrary statistics. It is, however, a peculiarity of variola that it affects childhood, and after thirty years becomes very much less.

Prof. CROCO, of Brussels, replied that medical statistics are especially deceptive. On the ground of his own experience in the epidemic of 1865, with 4000 cases, he believed the practice did protect. Among the vaccinated the mortality was 2 per cent.; among the others, 70 per cent. Nor could the fact of their slighter sickness be treated as an accident. Vaccination does not absolutely protect, but does lose power with age. He believed there was no scientific difference between human and animal lymph, that its essential properties remained the same, and that a station for the supply of original lymph was of the greatest value in times of need.

Dr. GUNTHER, of Dresden, did not believe that animal was stronger than human lymph, nor that dangerous diseases were conveyed by vaccination. He was strongly convinced that it did protect, and also lessened the mortality, in his experience from 30 per 100 to 3 per 100.

Dr. SCHNEIDER, of Java, from twenty years' trial believed in its protecting influence. An epidemic travelling westward was made to *jump over* his district by universal vaccination.

Dr. MULLER, of Berlin, made an earnest speech, defending his quoted statistics and showing wherein they were imperfect. He could assure the delegates that after inquiry into the case of every death among children in Berlin for a year, he could find not one well-vaccinated child who had died of smallpox. He had no doubt that vaccination is a protection against smallpox. Further, he had never seen animal virus produce severe local action, neither when retrovaccine nor genuine lymph was used. He agreed with the referees. As for himself, he had only experimentally used genuine lymph. He cited the cases of Dr. Pissin, who every year has vaccinated many children again and again to no purpose. Dr. MULLER would use genuine lymph, and the pustules came finely. He cannot, therefore, free himself of the idea that animal lymph is not so sure. He denied that many persons took smallpox between ten and twenty, but the disease begins to increase after twenty years, and it occurs up to thirty and forty years. He willingly used animal lymph to satisfy public opinion, though he did not believe in the idea of degeneration through repetition; he used the genuine lymph which was sent him, kept it in store, mixed with glycerin, and so was ready for a regeneration of lymph at any moment. He wished to say that glycerin-lymph would do more than had as yet been claimed. In no other way could so large a quantity be carried about. In no other way could he have supplied all North Germany in 1870-71.

Dr. EULENBERG, of Berlin, spoke next, referring to the unsafe light which statistics give. He considered that the statistics of vaccination and small-pox were not yet elaborate enough. We must be sure that the technique of the operation is correct, since upon systematic and expert performance of the vaccination depends its success, and a bad vaccination gives only imperfect protection. In statistical reasoning we must be sure that the cases in question were properly vaccinated, that the pustule had passed through its stages regularly and had not been destroyed afterwards. Only hospital and similar material is of use now. Technique, quality, and quantity are all to be factors of the investigation. Marson and Gregory laid great stress upon these, and had established how greatly the number of cases and mortality depended upon the proper enumeration of the sick and the proper condition of the scar. Marson concludes that the mortality among cases with ten scars is nil. But we shall have won a victory when the mortality is reduced to a minimum. If not a perfect protection, remember, "*remedium anceps melius quam nullum.*" "But I consider it a duty of the Congress to speak out loudly and openly how strongly they are impressed with the great importance of vaccination for the public good."

Vice-President HEBRA then closed the session.

SECOND SESSION.

The second session began at 9 A.M. of Tuesday, with Prof. WARLOMONT, of Brussels, for President, assisted by Dr. KOVACS, of Pesth, and Prof. SIGMUND, of Vienna, with Profs. SIGMUND, ZEISSL, and REDER as a committee of reference.

Prof. WARLOMONT is a slightly-built, very handsome gentleman, with a pale alert face, high brow, scanty white hair and side whiskers, and exceedingly courteous bearing. He opened the session with a speech in French, declaring that the question for discussion, "The Prevention of Syphilis with Reference to the Regulation of Prostitution," was one which in Belgium had received the most constant and devoted attention. By the law of 1836 the surveillance of persons and places notoriously devoted to debauchery belongs to the assembly of mayor and aldermen. It takes the proper steps to guarantee security, morality, and public tranquillity. The common council make such rules as they deem necessary and useful. Yet the government is not ignorant concerning the good management of the service. It has considered it a duty to inform the local authorities of the importance of the duty intrusted to their care, and provided an outline or type containing all the details necessary to secure morality and good hygiene. By these means syphilis has been reduced to so small a minimum that it would be extinct were it not for the importations.

The referees brought forward a law for the prevention of syphilis and printed it for distribution. It remarks that the diseases in question, fraught with evils of the greatest moment, are almost everywhere increasing. Since individual efforts fail to restrain it, associated efforts must be made. Better than any other contagious disease its natural history is known.

Wherever medical advice has weight, it is restrained (Brussels, Piedmont). Some degree of success can be obtained by measures directed against it at its very inception; but such measures belong to legislation and government. The great source for the spread of the disease is prostitution in its various forms, but especially that called clandestine. Organized bodies incompatible with marriage—troops, marines, as well as domestics and laborers—favor its propagation. So too with great centres of population, pilgrimages and campaigns, midwives, nurses and attendants, foundlings, certain trades, as glass-blowers, cigar-makers, etc. As social life cannot be readily changed, and means of intercommunication rapidly increase, the simplest and easiest check to the spread of syphilis is legislation. But local legislation is imperfect. Therefore international regulation is the greatest means of relief, analogous to that against cholera, variola, yellow fever, and rinderpest. The details should be in the hands of experts, and the rigid execution of them must be demanded of the authorities. Only experienced and trusted physicians should be called to the work, and all of the profession should be thoroughly trained in the knowledge of the subject, for the sake of driving out quacks, so often sought because of an idea that regulars are ignorant of the disease. They recommend that syphilis should cease to be a specialty of certain physicians, the establishment of dispensaries, gratuitous consultations, hospitals, and public instruction on the nature of the trouble. A law was formulated by Messrs. Crocq and Rollet at the Congress of 1867, discussed at Florence, and laid over until the present meeting. The law which this committee brings forward is as follows:

1. *Organized surveillance of prostitution*, especially the clandestine, with all possible means of assistance, under the direction of a national board of physicians and experts. As examples they point to Brussels, certain towns in France, and Piedmont.

2. *Particular surveillance of venereal diseases* in all corps, civil, military, and marine, all associations the members of which can only with difficulty or not at all be married, as in various trades, secret societies, fairs, markets, and sea-ports.

3. Control of midwives, nurses, and nursery-maids, foundlings, rigorous control of vaccination, circumcision, certain trades, as cigar-making, and *periodical examination of the syphilitic a certain time after treatment*.

4. *Delicate and yet sufficiently clear instruction* on the subject, given by the physicians of corps, companies, and schools, with the insertion of like information in the regulations of such bodies and as regards places for treatment.

5. *Establishment of consultation offices*, in number, form, and arrangement, with regard to the special needs of individuals, so that modesty and social position may be regarded. Obligation of all corporations as well as unions of workmen to provide a sanitary service for their associates, with instructions to their medical men to specially regard syphilis.

6. *Compulsory admission of patients to hospital*, with separation of the notorious prostitutes.

7. *Thorough education of physicians* in the diagnosis and treatment of venereal diseases, the establishment of special clinics, and rigorous examinations before admission to practice.

8. *Appointment of trained and learned physicians* to the supervision of the hospitals, with honorable remuneration.

9. *Severe but just penalties* for all infected prostitutes who neglect to seek medical aid.

10. *Assumption by the state of all the expenses*, where the districts or the sick cannot be obliged, or are not able, to pay.

11. *Periodical international conferences* on the subject.

12. *Election of committees* for the treatment of the various questions which may arise, with the eventual choice of a central committee to take charge of all matters relative to the subject.

In addition to this most interesting plan, an outline of measures to prevent the diffusion of syphilis was presented in French by Dr. PIETRO CASTIGLIONE, of Rome. For interior measures against syphilis he advises complete control of prostitutes, registration, regular examinations, sequestration when infected, absolute suppression of amateur prostitution, power of interference on the part of the state, neither authorization nor prohibition, but absolutely perfect hygienic condition of premises and occupants, and special clinics at the schools of medicine. Also a new idea in the recommendation of an obligatory visit by the physicians of the corps to *soldiers, marines, and crews, to prisoners, government workmen, foundlings, and nurses*, and care of vaccinators and their vaccine, and, finally, the adoption of a uniform international supervision of the whole matter.

A most vigorous and enthusiastic discussion at once sprang up. Prof. SIGMUND, after remarking that the questions were to be discussed from the medical point of view only, and giving some historical details, continued that, owing to the great attention the subject had received, he and his colleagues Profs. ZEISSL and REDER could not hope to bring forward anything new, but were only in accord with the previous Congresses. We must try to discuss measures which are lawful, and, what is of most consequence, keep in view what is most practicable under existing circumstances and with the means at hand. Especially did he strongly recommend the thorough instruction of physicians as regards syphilis, and the publication and wide distribution of information on hygiene, which ought to be communicated to schools, societies, and all bodies of men. If we look over what the last four hundred years have done towards limiting and mitigating syphilis, we ought to be ashamed of its insignificance. But knowledge of imperfections is the first step towards a reform, which he hoped this deliberation might bring about.

Prof. REDER said they had introduced no new points into their programme, since they did not wish to lose sight of the object of their discussions,—the bringing about of an international law, or at least the furtherance of it. But such a law, in the nature of things, could only be in the line of principles. Details must be left to states. So with

prostitution; laws must come from the lawgivers, principles from medical men.

Prof. O. HJELT, of Helsingfors (Finland), said that the circumstances of the northern countries of Europe in regard to syphilis were not without meaning for our medical lawmakers. The idea of the assumption by the state of the cost of medical treatment of syphilis has already been for twenty-five years in practice in Finland: it is therefore well provided with ordinances to prevent the spread of the disease. In the larger districts the control of prostitution has been introduced; sailors returning from abroad are examined, and one has the right to demand the certificate of health from suspected persons. In spite of this, syphilis has increased in the last years to a remarkable extent, and has become a question of great moment. He has treated this subject, in a work shortly to appear, from a sanitary and statistical stand-point, his researches having been carried on in 45,613 cases of disease which he had treated in hospital during the last twelve years. In 1859 there were 2881, but in 1870 there were 6610 cases out of a total population of 1,700,000 souls. In 1859 there were 684 new or primary cases; in 1870 there were 1258. Of constitutional syphilis there were, in 1859, 1725 cases; in 1870, 4223; while of gonorrhœa there were 355 in 1859, and 563 in 1870. For the twelve years there was an average of 2.27 per 1000 treated in hospital. He refrained from explaining the causes of this great increase, denying, however, that immorality is one. He attributes much influence to the out-door habits of life in certain seasons, and their thoughtless hospitality in harboring every vagabond who chances that way. Syphilitic diseases of the skin are very common in Finland. He brought forward other statistics of great interest and value. In Sweden, where there is gratuitous treatment and an assessed tax for the same, from 1861 to 1868 there was an average of 1.24 per 1000 of population (at Stockholm 16.04); in Norway, from 1859 to 1870, a yearly average of 0.86 per 1000 (at Christiania, 7.66); and in Denmark 1.11 per 1000 (in Copenhagen, 14.89). He agreed with the principles of the programme, modified, however, for the exigencies of each country.

Prof. CROQU, of Brussels, gave the historical details of the institution of the present laws in Belgium, which have served as the type for all others since adopted in Europe, and have considerably reduced the amount of syphilis. He regarded it as certain that not all the diseases of the genitalia induced by coitus are venereal.

Prof. CASTIGLIONE, of Rome, agreed perfectly with the twelve points of the official programme. He wished for a legal and strict supervision of prostitution, isolated or concentrated, without the state mixing itself in the internal management of the houses; also to prevent the registration of prostitutes, giving occasion for any unfortunate mistakes, the isolation of infected persons, and clinical instruction.

Dr. ABDULLAH BEY, of Constantinople, agreed perfectly with Prof. SIGMUND and his associates, from his experience at home.

Various gentlemen then advanced verbal changes in the programme, or made short remarks of no great moment, and the recommendations of the committee were in principle accepted. The votes were to be declared on Saturday.

THIRD SESSION.

The discussion of the question of vaccination was resumed on Tuesday afternoon, Dr. ISIDOR NEUMANN, author of the well-known work on skin diseases, being the first speaker. He was a friend of the practice, bringing forward the following results from his experience in charge of a smallpox hospital :

Of 1148 cases there died 140—12.2 per cent.

“ “ were vaccinated 1030

“ “ “ non-vaccinated 91

“ “ “ doubtful 27

vaccinated there died 90— 8.7 per cent.

Of 1030 vaccinated there died 90— 8.7 per cent.
 “ 91 not “ “ 40—43.9 “

It is certain that the vaccinated have the disease less seldom, and in a lighter form. At the time of the last epidemic at Berlin there were 200,000 unvaccinated, 330,000 vaccinated, and 270,000 revaccinated. Of the first there died 14 per cent., of the second 2 per cent., and of the last 0.5 per cent.; from which facts it appears that the disease and death were much more frequent among the non-protected.

Dr. FRIEDINGER, of Vienna, strongly defended Jenner as against Dr. Hermann, giving some particulars of the opposition in England, and the final triumphant success of the practice. In 1856 only two out of five hundred and thirty-nine physicians declared themselves opposed to vaccination. He was in favor of humanized lymph, and vaccinating from arm to arm; agreeing with Dr. Müller, of Berlin, concerning the occasional uncertainty of cow-lymph. Dr. Simon, of London, supports him in this. As regards methods of preservation of the lymph, he did not think highly of the glycerin method.

Dr. MARKOWICI, of Bucharest, declared that the asserted increase of tuberculosis, scrofulosis, etc., from vaccination is untrue. The reason is to be sought in the bad hygienic conditions of the people. The protective power becomes exhausted, wherefore the need of revaccination. Varicella is a different disease from variola and varioloid,—distinguished from both by its pathological characters.

Dr. MEDOVIC, of Belgrade, from his experience in Servia favored enforced vaccination.

Dr. LOWI, of Vienna, recommended animal lymph.

Dr. MAZZON, of Kiew, declared that vaccination, though not absolutely protecting, shortened the disease and reduced its mortality.

Dr. VON BASTAU, of Breslau, quoted favorable statistics from the epidemic of 1871-72, and believed that the protection was so diminished by age that revaccination should always occur about the age of fifteen years. Variola after protection was much less severe.

Dr. GERMAN, of Leipsic, felt obliged by unfortu-

nate experience to declare himself opposed to vaccination. He considered it a prolific source of the communication of syphilis, and read extracts from a pamphlet which he had circulated, in support of his position.

Dr. KNOPFLER was astonished that an active physician could be an opponent of vaccination. On the sick-bed one can better observe the difference between the protected and the non-protected than in statistical tables, which latter lead to many errors. He wished the Congress to declare in favor of compulsory vaccination, under control of specialists.

Dr. KAPOSI then summed up the results of the debate. The opinion was almost unanimous in favor of compulsory vaccination. Only three debaters, and that on insignificant grounds, had declared against it. Their statistics have no weight against the mass on the other side. They have made it appear that the non-vaccinated were safer than the vaccinated. As regards the kind of lymph it appears certain only that both kinds may be used.

Prof. HEBRA then formulated the opinions of the Congress in the following resolution:

"The Third International Medical Congress declares vaccination indispensable, and advises its universal adoption."

Before the vote was declared, the meeting adjourned.

(To be continued in our next.)

ALCOHOL.—Rabow (*Inaug. Diss.*, Strasburg, 1872, and *Centralblatt*, 1873, 336) tries to show, in opposition to previous experiments of Binz and Bouvier (*Centralblatt*, 1871, p. 801), that alcohol does not prevent a febrile rise of temperature. He reports a case of peritonitis from perforation, in which the temperature rose from 38.8° C. to 38.9° within four hours, notwithstanding the administration of thirteen tablespoonfuls of Hungarian wine (equalling about three-fourths of an ounce of absolute alcohol, or an ounce and a half of brandy). This result can hardly be regarded as astonishing, or as furnishing any strong proof against the views previously held. He also took one or two tablespoonfuls of brandy, or twenty-five c. c. of alcohol, at various times, and determined a rise of temperature of 0.01 to 0.03 C.

Daub (*Cbl.*, 1873, 466) criticises the above experiments, by showing that a thermometer held continuously in the axilla for an hour or more often steadily rises 0.03 or more when no alcohol is taken. (That is, the axilla, kept continuously closed, approximates more and more to the interior cavities of the body.) Daub correctly remarks that measurements in the axilla are sufficiently accurate for clinical purposes, but not for physiological experiments, where it is a question of a small fraction of a degree.

Daub further showed that, in a person unaccustomed to alcohol, small doses caused a diminished rectal temperature, as compared with that of other days when alcohol was not used. As the person became accustomed to the alcohol, the result failed to be observed. In two children, one with chronic osteitis and the other with caries of the tibia, no heat-lowering effect took place.

Magnan (*Archives de Physiologie*, 1873, Nos. 2 and 3) gives the results of his experiments upon alcohol and absinthe, as follows:

The immediate effect of alcohol, in a sufficient dose, is, in every animal, drunkenness.

The prolonged use of alcohol provokes, in the dog, besides the drunkenness which follows the administration of each successive dose of the poison, phenomena progressively more marked, which exhibit us the gradual evolution of alcoholism: from the fifth day of the intoxication, irritability and sensitiveness are observed; ten days after, illusions and hallucinations in the night; at the end of a month, delirium night and day.

The prolonged use of alcohol gives rise, in the second month, to trembling, which shows itself first in the hind feet, then attacks the fore feet, and extends progressively to all parts of the body. In no case is an epileptic attack provoked. Finally, the digestive troubles and various complications recall the conditions causing death in men suffering from the chronic effects of alcohol. The anatomical lesions of alcoholism in the dog show, in different degrees, 1st, steatosis (liver, kidneys, heart); 2d, tendency to chronic irritations (meninges, spinal cord, pericardium).

Essence of absinthe, in small dose, determines dizziness and muscular jerking in the anterior parts of the body; in the large dose, it causes epileptic attacks and delirium.

To the first stage of the attack of absinthism (tonic convulsions) correspond dilatation of the pupils, injection of the papilla and fundus oculi, and congestion of the encephalon,—phenomena which do not agree with the generally-accepted theories as to the mechanism of epilepsy.

Animals deprived of their cerebral lobes present, under the influence of essence of absinthe, epileptic attacks and jerkings similar to the convulsive phenomena in those animals which have undergone no mutilations.

After the section of the cord below the medulla oblongata, the intravenous injection of the essence of absinthe provokes, first, a bulbar attack (tonic and clonic convulsions of the head, with foaming at the mouth), and then a spinal attack (tonic and clonic convulsions of the trunk, with expulsion of urine and fecal matter).

The isolated action of each segment of the spinal axis in the regions which it supplies with nerves accounts for the necessary influence of the whole of the organ in the production of the complete attack of epilepsy; and, on the other hand, taking into the account the sudden and immediate loss of consciousness, one must necessarily admit the direct intervention of the whole cerebro-spinal axis in the production of the epileptic attack.—Dr. E. T. Edes, in *Boston Medical and Surgical Journal*.

CHOLESTEATOMA OF THE PETROUS BONE (August Lucae: *Archiv f. O. N. F.*, Band I., Heft 4).—This author has contributed a very valuable and original paper on the above-named subject. He says that in a vast majority of cases of this form of disease a purulent discharge from the middle ear, with a greater or less defect in the membrana tympani, was found. The favorite seat of the disease is the antrum mastoideum.

The author also notes the constant presence with this disease of granulations and polypi developed from the mucous membrane of the middle ear.

Careful microscopic examination of these polypoid excrescences on the mucous membrane of the middle ear showed that in many instances they are covered with thick, pearl-colored epidermis. Transverse sections of the excrescences showed that newly-formed epidermis—that is, *heterologous tissue*—was present. From this it is fair to conclude that purulent inflammation of the middle ear with granulations may, in a way unknown to us, lead to a proliferation of epidermis, the old cast-off cells of which collect in the cavities of the middle ear and form at last a cholesteatoma, or what the author calls "Perlgeschwulst" (pearly tumor.) C. H. B.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 11, 1873.

EDITORIAL.

NATIONAL SANITATION.

AT the recent meeting of the British Medical Association, Dr. George W. Hastings, Vice-President of the Section on Public Medicine, in the course of an address upon public hygiene, remarked upon the backwardness of our government in these matters. Although evidently moved by the kindest feelings towards us, the truth forced him to the statement that we are far behind England in public medicine. If he had told the whole truth, he might have said much more than this: he might have declared that in the greater part of our country public medicine has no existence,—the American citizen expecting as little and receiving as little protection for his life against the insidious disease or the open-handed pestilence as does the Comanche or the Arab.

It is evident that something ought to be done. Shreveport, New Orleans, Memphis, ay, even New York and Philadelphia, yield up their thousands of unnecessary deaths; yellow fever, cholera, smallpox, chronic arsenical poisoning, sewage contamination, impure air, crowded tenement-houses, rampant prostitution, and the thousand curses which seem the birthright of modern civilization, lie heavy upon the people, who live, and sicken, and die; yet no man says aught, or at least no man having authority. To the fierce, anxious populace that crowd the mustering places after an important election; to those hilarious over political victory or sullen with political defeat;

to the professional politician greedy for himself, studying how he can best lead and control that mass he both fears and despises,—the voting populace,—to such, questions of hygiene seem but trifles, unless indeed when some frightful epidemic rocks a community to its foundations.

Within the last year or so, however, a few physicians have begun to raise their voices over this dance of death, and to call attention to the national recklessness. What shall be done? Are we to have merely local boards of health,—some (very few, however) good and efficient, some useless, some worse than useless—mere masks to hide the rottenness underneath,—each of them caring only for the little community over whose vital interests it is supposed to preside.

Is it not possible to find some plan by which a central authority can be established, at least a binding cord to unite, to harmonize, to render efficient these various bodies?

We cannot but believe that Congressional legislation might, if wisdom were granted our rulers, solve this problem. What that legislation should be is a question of great importance, not to be decided hastily, but only after full and wide discussion.

Many even of the best-informed of our profession have but little idea of what the duties of a hygienic inspector should be. Very few, indeed, have any practical knowledge of the work. Under these circumstances, let us make haste slowly. Office-seeking is possible even in a physician. In some of our great cities certain men have drifted into a more or less complete knowledge of hygiene, and some no doubt have entered upon its study because they smell the battle afar off and see prospects of lucrative and honorable office,—*otium cum dignitate*. Is not that worth a little plotting, a little labor, even a little present weariness of the flesh?

There will come up for discussion by the American Public Health Association, at its meeting in New York in November next, a resolution to the effect that a National Sanitary Bureau should be established in connection with the Interior Department. Is it yet time for this? We know of no one who urges the affirmative to this question, except the very few who may be fairly presumed to have a direct personal interest in the creation of new offices. Rather than make such radical legislation, let us first collect data and opinions bearing upon the subject of public hygiene, and upon the State and national legislation primarily desirable and practicable. And to gain the confidence and support of the medical profession of the country, without which we believe the attempt will fail, we should

like to have these data and reports presented by some competent and, at the same time, disinterested authority.

Judging from what it has done in the way of collecting and publishing information for the profession, we believe that the medical department of the army could do well the preliminary work required; and until this is done we deprecate the urging of hasty legislation on the subject.

The Surgeon-General of the army can avail himself of the services of medical officers familiar with statistical inquiries, and is already furnished by the fine library of his office with much valuable material for this inquiry; and, what is even more important, we may feel sure that the report will not be prepared in the interest of any individual or party.

We believe that in a few years there will be a National Sanitary Bureau at Washington; but we want it kept out of politics, and we do not want its first stages to be under the direction of a department in which the appointments are governed by political considerations, and in which the very first step will be a scramble for office.

CORRESPONDENCE.

LONDON LETTER.

Thousand-Guinea Fees—A Brilliant Career—Epidemic of Typhoid Fever among the Doctors—Poisoned Milk—Mrs. Garrett Anderson.

THE Highland holiday of our London physicians and surgeons has been interrupted by an incident productive of some rather curious illustrations of professional practice and feeling. A very well-known and wealthy man, who has many friends and personal acquaintances among consulting practitioners in London, was seized with a very severe illness at his hunting-lodge. His friend Sir Henry Thompson was near at hand, and was summoned. He came over at once, and, finding his friend dangerously ill, was fain to stay with him in his time of need, and began a close attendance, which lasted for nine days and nights. He was offered, on resigning the case to Sir William Jenner, who was summoned by telegraph, a check for a thousand guineas, but steadfastly refused to take any fee whatever, alleging that he had attended solely as a friend and would not otherwise have undertaken a case of the kind. This is the second time during a few months that the same surgeon has returned a check for a thousand guineas from motives of delicacy. I have mentioned in a previous letter that, knowing that the family of the ex-Emperor Napoleon were not in possession of large means, he returned a fee of a thousand guineas in that case. It is not often

that the same surgeon receives fees so large as to afford the opportunity of dealing with them in a manner so splendidly liberal and delicate, and perhaps it is as rare that he should insist upon doing so. But Sir Henry Thompson is in receipt of an exceptionally large income from the successful practice of his profession, and he is a man of great decision, clearness, and liberality of mind. He is a man who has reason to be satisfied with his career, and of whom we in England have reason to be proud. Commencing the study of surgery rather late in life, and not graduating, I believe, till the age of thirty, he has by the sheer force of intellect and work won his way to the highest eminence and success in practice, to a fine fortune, a splendid social position, and a world-wide reputation. He is still a young man, and his career has been as rapid as it has been brilliant. Nor has it involved sacrifice of other pleasures and pursuits. He is an artist of high attainments,—perhaps the best amateur in oil-painting in England: his pictures are not only well hung at the most difficult and eminent of our exhibitions,—the Royal Academy,—but command a fair market price against those of professional artists, when he is disposed to part with any of them. He is an excellent writer and a man of thoughtful habit on other than medical subjects: his paper in the *Contemporary Review* on the Efficacy of Prayer, addressed to Professor Tyndall, opened up the controversy of which the echoes reached your continent; and he has all the other accomplishments, as a sportsman, etc., which suit the character of an English gentleman. This brief outline of the elements of a singularly successful character and career is only noteworthy as affording encouragement to others and furnishing the materials for contemporary history.

A very singular and disastrous circumstance has occurred in the principal medical quarter of London, which took place at the close of the season (end of July), but of which the effects have been felt throughout August and have not yet died away. The consulting practitioners of London congregate together chiefly in a few streets and squares most centrally situated: this is chiefly a matter of convenience, and to some extent perhaps of fashion. Brook Street, Harley Street, Grosvenor Street, and Queen Anne Street, and the neighboring squares, are the great centres of medical residence for the leading metropolitan practitioners.

Much attention has been directed in London lately to the necessity of procuring a pure and unadulterated milk-supply. More than one company has been started of late years, headed by gentlemen of respectability and position, whose names afforded a guarantee of fair dealing, for the purpose of inaugurating a pure milk-supply on a large scale. One such company, seated near the medical district,—The Dairy Reform Company,—has had a great and deserved success. The precautions taken to prevent the addition of water or the abstraction of cream were very great, and the milk supplied was undoubtedly pure. The doctors largely patronized the company.

Towards the middle of July we were all rather grieved

to hear of successive attacks of typhoid fever in the families of medical men in this district: first it was Dr. Murchison's children, then Mr. Spence Watson's, Dr. Tuller's, Mr. Maunder's, Dr. Buchanan's, Mr. John Wood's, and so on, till it seemed that the whole medical community were to be decimated by typhoid. Nor was there anything to explain the mysterious outbreak. Some of the houses had been not long before most carefully overhauled, and in most of them the sanitary conditions had been well regulated. The sewers were trapped and ventilated, the waste-pipe of the water-cisterns was not connected with the sewers, and all the water was filtered. Presently a clue was suggested. Dr. Murchison's children had been attacked in two sets, and under peculiar circumstances which led him to think, on consideration of certain details, that it was possible that the milk which they drank might be the source of infection. He communicated this suspicion to some of his neighbors, and in the course of an hour or two it was found that nine families in the neighborhood who were suffering from typhoid were all drinking this same milk, and this seemed to be the only condition in common.

The medical officers of health of the district immediately (August 4) communicated these facts to the company, and suggested that they should discontinue the supply of milk from the suspected source. Strong in their consciousness that their milk was pure and unadulterated, the company refused to see in the matter anything more than a coincidence, and declined to stop the milk. Day after day brought, however, fresh evidence. In a day or two thirty-two families were ascertained to be suffering from typhoid fever, of whom thirty were customers of the Dairy Reform Company. Presently a hundred affected families in all, including five hundred cases, were found to be using this milk.

Meantime a government inspector, Mr. J. N. Radcliffe, accompanied by other persons on behalf of the company and the parish, had inspected the farms from which the milk was supplied, had found typhoid fever to exist on one of them, and that the cess-pool was in dangerous proximity to the well in which at least the churns and milk-cans were dipped and washed and then not wiped but left to dry.

A great number of singular examples attested the fact that the milk was indeed the lethal agent. Thus, in the family of a noble lord in Grosvenor Square all the servants drank Dairy Reform milk, and the family milk direct from the estate: five of the servants were down with fever, and none of the family. In another case two servants in a house free from fever and in a distant part of London drank largely, one day when they were out, of the Dairy Reform milk: both were down with the fever, and none of the rest of the household. The family of the Dowager Duchess of Buckingham drank of the milk from the same can which supplied her next-door neighbor, a physician: the fever seized her household; the physician's household were exempt; he had all the milk which came into the house boiled. A number of similar instances strengthened the statis-

tical argument irresistibly, and proved the case. The company had stopped the supply of milk at last, on receiving a telegram from their agent stating that typhoid fever existed on the farm in question (although they had previously been assured by the farmer that there was no disease there whatever). But their long delay in doing so, after the propriety of this course had been suggested urgently by Dr. Whitmore, Dr. Murchison, and Sir William Jenner, has been the subject of severe comment, and is likely to lead to legal proceedings.

As a special item of London gossip during holiday-time, I may mention that Mrs. Elizabeth Garrett Anderson has a baby. Her energetic denial that she was *enceinte* was written to Dr. Sieveking not more than six months before her confinement. So that even the most learned ladies may make mistakes in such matters. And this is not the only mistake involved in that letter; for it was an error in taste as well as judgment, which surprised Mrs. Anderson's friends, for she is a woman of excellent sense and discretion, and her conduct has invariably been such as to win for her respect and esteem. She has lately been elected a member of the British Medical Association.

GLEANINGS FROM OUR EXCHANGES.

LATENT GONORRHOEA IN THE FEMALE SEX.—Last year Dr. Emil Noeggerath, of New York, wrote an elaborate paper, which was published in Bonn, and in which he endeavored to show that "certain diseased phenomena in the female organs which have hitherto been considered as separate and treated independently possess a common basis, from which they, collectively and separately, take their origin,—this being nothing more nor less than gonorrhœa." He undertook to prove that, with very few exceptions, the wives of such husbands as have at any time of life contracted gonorrhœa not only suffer as a consequence from such serious affections as acute, chronic, or recurrent perimetritis, oöphoritis, catarrh of the genital passages, etc., which he believes to be practically incurable, but that they are also, as a rule, sterile, or if they do become pregnant they either abort or bear only one child.

Dr. Noeggerath states that cases of uterine and connected disease are therapeutically divisible into two classes, the one series of cases being readily cured, the other proving excessively persistent, and that the intractable cases are really made so in consequence of the husbands of these patients having at some period of their lives, probably long before marriage, suffered from gonorrhœa. He holds, moreover, that, though time diminishes the intensity of the infection, yet gonorrhœa in the male as well as in the female continues to exist for the whole of life, in spite of apparent cure, and that there exists a latent gonorrhœa in both sexes which may evoke in a hitherto healthy individual either its own symptoms or those of an acute gonorrhœa. Dr. Angus Macdonald summarizes this essay as above, and details seven cases occurring in his own practice which bear upon the subject, concluding from them that "it is sufficiently evident that gonorrhœa in a merely subacute, if not even in an exceedingly chronic and apparently cured—*i.e.* latent—form in the husband, and one which, in the female, produces symptoms merely of a slight leucorrhœa, differing in general appearance little if at all

from ordinary leucorrhœa, may prove a complication fraught with extreme danger to the female, and, in the puerperal stage, one likely to lead to a dangerous and even fatal form of puerperal fever." He believes, however, that Dr. Noeggerath exaggerates somewhat the extent of the influence of gonorrhœa, and that he is mistaken in regarding it as an incurable disease, but thinks that we ought to be a very great deal more guarded in giving our permission of marriage to young men who have within a short period contracted a gonorrhœa or who suffer from a gleet discharge, as he considers it proved to a demonstration that "if a man marry with the slightest shade of a gleet he exposes his wife to the possible risk of great misery throughout her menstrual life, as well as to great risk of death in case she becomes pregnant."

In diagnosing the gonorrhœal form of leucorrhœa, the following points are of great importance. The discharge is yellowish-colored, as if mixed with pus; non-transparent as it flows from the cervix uteri, which is usually surrounded with a deep-red erosion some lines in width; the uterus is tender, more particularly in its lower part; the vulvo-vaginal glands are enlarged; the vulva is sensitive, and there is an inflammatory catarrh of the glands of Bartholini. It is also the rule to see "on separating the labia minora from the remains of the hymen, between the first and the under lateral caruncula myrtiformis, an intensely red point, covered over with glossy mucus, from which, as a centre, a red streak, constantly becoming fainter, stretches upwards and outwards, and, gradually becoming pale, passes over into the color of the surrounding mucous membrane." Inflammation of the urethra at an early stage of the disease is of great value, but it soon passes away; in addition we usually have chronic vaginitis and vaginismus.—*Edinburgh Medical Journal*, June, 1873.

CUTANEOUS CYSTS.—The following is an abstract of a short paper upon "a case of numerous cysts scattered over the body," reported by W. Allen Jamieson in the *Edinburgh Medical Journal* for September, 1873. The patient was a man forty-five years of age. The disease was characterized by some two hundred and fifty tumors, varying in size from a pea to a large nut, scattered over the surface of the body. They were situated immediately beneath the skin, which was freely movable over the smaller but slightly attached to the larger ones. Over most of the tumors the color of the skin was unaltered; over a few it was reddened; while over one or two of the largest it was greenish. Fluctuation could not be detected in the smaller nodules, which were hard and gristly, but was quite distinctly felt in the larger tumors. In appearance they bore a close resemblance to the common wen. The commencement of the trouble dated back one year. The general health had become greatly impaired; the man had emaciated, and was confined to bed. One of the tumors was excised for examination, but during the operation the cyst-wall gave way, and a turbid, brownish liquid escaped, which upon microscopic observation showed numerous epithelial cells. The termination of the case is not reported. A more detailed as well as more accurate account of the disease would have made the case of greater value.—L. A. D.

In the Italian section of the Vienna Exhibition, Dr. Marini exhibits, among an assortment of human feet, hands, legs, arms, and busts of shrivelled proportions and deep-brown color, a large, round plateau, evidently of hard and polished material, which has been likened to stale gelatin or potted boar's head. It is a conglomerate of specimens illustrative of an art invented by him,—the petrification and mummification of human corpses. It was this very Dr. Marini who petrified Maz-

zini, and executed his work so well that the admirers of the arch-conspirator proposed to set up the corpse on the Capitol and save Italy the expense of a statue. The preparations are weather-proof, and will take on high degrees of polish. His mummified specimens, by a process known to him alone, can be restored to their original size and elasticity; while the petrified ones are as hard and possibly as durable as granite. The top slab of the table is composed of muscles, fat, sinews, and glandular substance, all petrified together in a block, the surface of which has been planed and polished until its face resembles marble. Certificates from Nélaton and other distinguished surgeons are attached to the specimen-limbs, setting forth that the limbs in question had, for the satisfaction of the certifiers, been restored to their pristine softness and pliancy by Dr. Marini.—*Lancet*.

DIGITALIS.—M. Gaunot, in the course of a paper published in the *Gazette Médicale de Paris*, on the action of digitalis, says, "When digitalis or digitalin is administered for some time to a man in full possession of sexual powers, these become gradually weakened, the propensities disappear, formation of the liquor seminis diminishes and may at last cease altogether. The anaphrodisiac properties of the drug are the secret of its good effect in spermatorrhœa."

Dr. Little recommends the use of digitalis in febrile cases in which stimulants are either not well borne or are contra-indicated, as where renal affection is present. He has given half-drachm doses of the tincture every three or four hours in typhus, enteric, and rheumatic fevers, with very favorable results.—*Edinburgh Medical Journal*, July, 1873.

OLEATE OF MERCURY IN TINEA CIRCINATA.—Dr. Leonard Cane, in the London *Lancet* for August 16, 1873, recommends the use of the oleate of mercury (ten per cent. strength) as being of particular service in tinea circinata, several applications being sufficient to destroy all trace of the affection. It produces no staining or injury to the skin, nor is the application attended with pain or other unpleasant effect. The preparation is said to penetrate into the sebaceous glands, hair-follicles, and even into the hairs themselves, the mercury being in a state of solution in an oily medium. The penetrating power of the oleate may be increased by adding a small quantity of ether (one part to eight) to it. Dr. Cane records several cases where he has employed the oleate as a parasiticide with satisfactory results. L. A. D.

TREATMENT OF DIPHTHERIA.—Dr. Lolli strongly recommends the following measures, having found them extremely efficacious in a great variety of cases. 1. Avoid cauterizing, except when gangrene occurs. 2. Do not have recourse to bleeding, purging, or emetics, unless you are forced to do so by exceptional symptoms. 3. Diet, according to appetite; but at all events generous. 4. Do not interfere with the functions of the skin; or rather promote them by rest in bed, poultices, sinapisms, etc., and persevere until, from the general or local symptoms, it may be supposed that the morbid principle has been eliminated or destroyed. 5. Use the following mixture as a gargle, or apply with a camel's-hair pencil every second hour, or employ as an inhalation if the disease has reached the larynx:

- R Lime-water, f3iv to xij;
Solution of perchloride of iron, f3ss to f3ij;
Carbolic acid, gr. j to xx;
Honey of roses, f3j.

Shake the bottle well. The mixture may be largely diluted with water or tea and given internally.—*The Lancet*, Aug. 16, 1873.

COMPRESSION OF THE FACIAL ARTERY FOR EPISTAXIS (*Rev. de Thérap. Méd. Chirurg.*, and *Gaz. Med. Ital. Lomb.*, May 17, 1873).—Dr. Marvin, of Geneva, alludes to the disagreeable process of plugging the nares either with Bellois' sound or an elastic urethral sound, and states that he finds the following process preferable: As the blood generally comes only from one side of the nose, and most frequently from the anterior third of one of the nasal fossæ, he merely compresses the corresponding facial artery against the superior maxilla near the angle of the nose. The afflux of blood to the cavity of the nose is thus diminished, and the epistaxis ceases almost instantly. Persons suffering from excessive nasal hemorrhage on the streets, boats, or cars, may thus be readily and promptly relieved.

Bessières, in *La France Médicale*, 1873, recommends plaster of Paris for arresting epistaxis. Plaster is known as a hæmostatic in cases of leech-bites, cuts, and excoriations. The mode of using it in epistaxis is as follows: Sift a spoonful of unslacked plaster through a coarse sieve, place it in a tube of paper or light card-board, and blow it forcibly into the nostril, after having caused the patient to blow his nose.—*New York Medical Journal*.

SIMPLE METHOD OF TESTING PEPSIN.—The London *Lancet* gives the following rule:

Boil an egg for an hour, and cut a portion of the white into the thinnest possible slices. Take a two-ounce wide-mouthed bottle and introduce into it seventy-seven grains (5 grammes) of the sliced-white of egg, one and a half grains of pepsin, four minims of strong hydrochloric acid, and four hundred and twenty minims of distilled water. Place the bottle in a water-bath, and keep it for four hours at a temperature of 100° Fahr. A higher temperature (not exceeding 120° Fahr.) causes more rapid digestion; but it is, perhaps, better to work at about the temperature of the stomach. At the end of the experiment all the albumen should have been dissolved, nothing remaining but minute quantities of fibrous or membranous matters.

NEURALGIA OF THE TESTES.—J. Lazarus (*Wien. Med. Presse*, No. 30, 1872), in regard to the etiology of this affection, enumerates, among the lesser-known causes, chronic disorders of digestion, which are often accompanied by pain in the testicles; also, long abstinence from sexual intercourse, when it is apparently the consequence of a temporary debility of the virile powers, can give rise to neuralgia. Besides paying attention to various casual indications, the author has had remarkable success, in many obstinate cases, by the internal administration of sulphate of zinc (0.2 to 200), three times a day, one tablespoonful, as also hypodermically injected behind the scrotum of a solution of the same salt (0.06 to 12).—*New York Medical Journal*.

BURNS.—Glycerite of lime used in burns is said by De Breyne to soothe the pain and to prevent inflammation or diminish its intensity: it is prepared from recently-slacked lime, one part; glycerin, fifty parts; chlorinated hydrochloric ether, one part.—*Medical and Surgical Reporter*.

ADHESIVE PLASTER.—To render sticking-plaster which has become brittle by age, and has lost its adhesive qualities, adhesive, coat it with oil of turpentine, by means of a sponge, and leave it exposed for a day.—*American Practitioner*.

ASTHMATIC PASTILES.—Take of stramonium-leaves two parts, nitrate of potassa one part. Reduce to a coarse powder, and put up in paper cones weighing half an ounce each.

MISCELLANY.

HOSPITAL CONSTRUCTION.—The final report of accounts for the building of St. Thomas's Hospital has been presented, and some extracts from it are published in the *Times*. The following, which relates to the outlay on the buildings, will be read with interest:

"The total expenditure, irrespective of the cost of the site and of the extensive concrete foundations required by the exceptional character of the ground (half of the site having been reclaimed from the river), may be thus classified:—Mr. Perry's account for the buildings, £346,377; ditto, for sundry wood fittings, £6500; for warming, ventilating, and hot-water services and ward stoves, £11,345; for hydraulic lifts, etc., £5229; for gas mains, pipes, and fittings, £3765; for cooking-apparatus in the principal and other kitchens, £875; lavatory and bath fittings, £1667; stoves and chimney-pieces, £1721; electric communication and bells, £918; engineers' work in the dispensary and other laboratories, and fittings in chemical laboratory, £1788; fire-appliances, £313; laying out the grounds and planting, £2820; sundries, £597—total, £383,948. Of this amount, the architect states that about £30,000 may be taken as the cost of the museum and school buildings, including fittings; £10,000 as the expense of erecting the home for the probationer nurses to be trained under the arrangement with the Council of the Nightingale Fund; and Mr. Currey estimates the cost of the extensive range of buildings required for the out-patients and casualty departments at £33,000, leaving £311,000 as the cost of the hospital, including the administration block, officers' residences, the chapel, the enclosure walls and railings, the river colonnades, hydraulic lifts, and all necessary fittings; and, as the hospital is designed for nearly 600 beds, the cost per bed is a little more than £530, with a cubic capacity of 1800 feet for each patient. The cost per cubic foot of the whole range of buildings has been about 9d., and it may be safely asserted that the cost of the hospital would have been largely increased had its erection been postponed to a later period. (It may be desirable to state the cost of the simple extension of a hospital built on the pavilion principle, with but two rows of beds in each ward, where only ward and nursing accommodation is required. The architect gives as the cost of one pavilion, containing 111 beds, with Sisters' rooms, nurses' dormitories, ward kitchen and offices, excluding, as before, the cost of special concrete foundations, as extracted from tender of Mr. Perry, £29,468: add for extras, being proportion of the actual result, £1472—total, £30,940, or nearly £280 per bed; and adding for fittings, lifts, gas, warming and ventilating arrangements, and electric communication, £4400—total, £35,340, or about £318 per bed.) It may be interesting to compare these figures with the cost of other hospitals. The Herbert Hospital, with a cubic capacity per patient of 1200 feet, cost £320 per bed, exceptional circumstances, as at St. Thomas's, having increased its cost. The Lariboisière Hospital

at Paris, with 606 beds (having but very limited out-patient arrangements, and needing much less extended corridor communication), is said to have cost £440 per bed, with a cubic capacity of nearly 1900 feet per patient. The Hôtel-Dieu at Paris, now in course of erection, is reported to have cost, with the alterations which have been found necessary, £600,000; and if the number of beds be reduced, as proposed, to 400, the cost per bed will be £1500, with a cubic capacity to each of about 2300 feet; but if the original number of 800 be adhered to, the cost will be £750 per bed. Taking, therefore, the average cost of the three great hospitals referred to, the average cost per bed appears to be a little more than £500, and the average cubic capacity 1800 feet, which figures nearly correspond with the results at St. Thomas's. It is believed, however, that the accommodation provided at St. Thomas's in ward-offices, etc., irrespective of the actual ward space, is far larger than at any of the other hospitals referred to; and it must be remembered that this is included in the cost per bed. The professional charges of the architect (including payments of £2252 to the clerk of the works) have been £13,032. The cost of furniture has been £10,084."

PATENT-MEDICINE VENDORS.—An action for libel was lately brought against the *American Agriculturist* by a Dr. Ryan, a patent-medicine vendor. Judge Brady, of New York, before whom the case was tried, gave the following opinion:

"1. A medicine that claims to be an antidote, but is not, is calculated to deceive, and is a fraud.

"2. The seller of a drug or medicine, who vends it with an unqualified statement of its efficiency, must take the consequences if his representations be untrue.

"3. That men should be held to a strict accountability who attempt to practise on the credulity of the afflicted."

We fully concur in this interpretation of the law, that any man who buys a nostrum advertised to cure a certain disease, and is made worse, or is not cured, can bring suit and recover damages from the vendor of said nostrum. We trust that those injured, or not cured, will apply for damages in such numbers as to frighten these unprincipled men into propriety.—*Canada Lancet*.

WHETHER the American politician is or is not a great sinner, he certainly receives such a share of abuse that it is to be hoped he is both pachydermatous and philosophic: to give him due credit, he must be, as he really seems to keep on the even tenor of his way unmoved. It has been reserved for our venerable and dignified cotemporary, the *Boston Medical and Surgical Journal*, to give the "most unkindest cut of all." In a recent editorial full of wrath at the virtuous teetotallers, it says, "We are actually subjected to these daily outrages by a miserable set of pie- and bean-fed politicians,"—an evident allusion to the windy and odorous nature of the food aforesaid. Alas for the flatulent politicians!

MARINE ANIMALS IN FRESH WATER.—At the present day, animals commonly supposed to be essentially marine are occasionally found inhabiting fresh water. In the inland fresh lakes of Newfoundland, seals, which never visit the sea, are common and breed freely. The same is the case in Lake Baikal, 1280 feet above the sea-level, in Central Asia; and, though these facts bear but slightly on my present subject, seals being air-breathing mammalia, yet in the broad mouth of the Amazon, far above the tidal influx of sea-water, marine mollusca and other kinds of life are found, and in some of the lakes in Sweden there are marine crustacea.—*Prof. Ramsey, in Popular Science Monthly for September*.

EXTRAORDINARY SWIMMING.—Mr. Maurice H. Richardson, of Fitchburg, a Harvard graduate of the present year, has just performed the extraordinary feat of swimming all the way from the stone pier at Falmouth across to Martha's Vineyard, a distance of seven miles and a half, in two hours and fifty-five minutes. A friend escorted with a boat, but gave no assistance. Our informant had the facts from Mr. Richardson himself. He has received an appointment as teacher in the Salem High School.—*Middlesex Journal*.

SIR HENRY HOLLAND closed his delightful volume of "Recollections," last year, with observing that the foreign journeys which he had been in the habit of taking annually for fifty years were probably at an end, and that "in future" (he was eighty-five as he wrote) he should restrict himself to a narrower circle. He has changed his mind, however. The gallant doctor has just left London on his ordinary two months' tour, for a place as distant from his home as Nijnii-Novgorod, where he trusts to see for himself a fair of which every one who knows anything of Russia has heard.—*Boston Medical and Surgical Journal*.

RETURN OF MENSTRUATION IN A SEPTUAGENARIAN.—Born in 1800, this lady menstruated regularly up to 1859, when this function ceased. In 1868 it again returned, and has now been perfectly normal in appearance and regularity ever since.—*Rivista Clinica di Bologna*, July 25, 1873.—*The Clinic*.

A WELL-MERITED COMPLIMENT.—Our distinguished contributor, Dr. S. Weir Mitchell, was the recipient of a complimentary dinner on his late return from Europe, given by some of his professional brethren.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM SEPTEMBER 30, 1873, TO OCTOBER 6, 1873, INCLUSIVE.

IRWIN, B. J. D., SURGEON.—When relieved by Acting Assistant-Surgeon Shearer, to comply with S. O. 187, c. s., A. G. O.

WATERS, W. E., ASSISTANT-SURGEON.—Granted leave of absence for twenty days. S. O. 154, Department of the Missouri, October 1, 1873.

WIGGIN, A. W., ASSISTANT-SURGEON.—Assigned to duty at Fort Walla Walla, and granted leave of absence for thirty days, with permission to leave limits of Department and apply for an extension of thirty days at Division Headquarters. S. O. 129, Department of the Columbia, September 18, 1873.

SATURDAY, OCTOBER 18, 1873.

ORIGINAL COMMUNICATIONS.

THE THIRD INTERNATIONAL MEDICAL CONGRESS.

HELD AT VIENNA, AUSTRIA.

Reported by FREDERICK W. RUSSELL, M.D.

(Concluded from page 26.)

FOURTH SESSION.

THE fourth session of the Congress began at 9 A.M. of September 3, with Dr. GUNTHER, of Dresden, for President, and Dr. TOMASSICH and Dr. DRASCHE for Vice-Presidents, with Dr. OSER, Dr. WITLACIL, and Dr. DRASCHE, as a committee of reference. The question under discussion was, "The Subject of Quarantine, with Particular Reference to Cholera."

A little four-page sheet of suggestions and propositions was distributed by the reference committee, of which the following is a brief summary:

The cholera conference at Constantinople in 1866 had declared for the universal adoption of quarantine against cholera, because that incontestably offers a strong guard against the entrance of the plague, when conducted on a rational basis and in accord with the demands of science. Moreover, the present rules of quarantine are of less injury to commerce than the loss produced by a single invasion of the disease. Cholera must be fought at its place of origin before the process of extension begins. Regulations must be established upon principles which govern its transmissibility. Sanitary lines, though troublesome in a crowded population, can do much towards preventing the extension of the disease. As a basis of discussion, and in reply to certain questions, they advance the following points:

1. The essential influence of commerce in spreading the disease is undeniable.
2. Cholera is a preventable disease.
3. Quarantine regulations theoretically offer a protection against the spread of cholera.
4. Practically, however, the protective influence is considerably reduced, or quite destroyed:
 - (a.) Because a complete prevention is impossible.
 - (b.) Because there is ample time for the spreading of cholera in all directions between the first cases and the establishment of official control.
 - (c.) Because the time of incubation of the disease is longer than the appointed time for quarantine, and also because a person sick with the premonitory diarrhoea can spread cholera.
 - (d.) Because the escape from quarantine of a single case is enough to incite an intense epidemic.
 - (e.) Because irregular licenses, and false statements of captains and the public, are not to be avoided.
 - (f.) Because in countries with established inland commerce the protection of quarantine is one-sided, and therefore useless.
 - (g.) Because, as inland trade increases, and the

net-work of railroads brings us nearer to the home of cholera, the power of quarantine must steadily decrease.

(h.) Because the hygienic conditions of the quarantine grounds not seldom tend as much to increase the pestilence as to check it.

5. The preceding facts give no clear demonstration of the sure advantage of quarantine. If, however, one country is preserved from the disease in this way, there are others which a much stronger quarantine does not save from fearful epidemics, and others which remain free in spite of notorious relaxation of quarantine.

6. From the great hinderance of quarantine to the interests of commerce, it is a question of the utmost moment to come to a clear decision as to its value. To this end an international commission is to be convened, to discuss these points, to fix upon the places for a sharp oversight, to report on the onward march of cholera, and to attend to the other causes of the spread of the disease.

7. Upon the grounds of these conclusions this commission is to frame an international law, from which no government, without permission of the others, can withdraw.

8. The decisions of the conference of 1866 are concise material for this purpose.

9. The isolation-laws of countries have to cease, at least for Europe.

10. Hospitals are to be constructed in accordance with hygienic laws.

11. The hygiene of trade by land and water is to receive particular attention at the hands of governments.

Dr. GUNTHER, after conveying his thanks for the honor conferred, expressed his strong hopes that through united effort a long step on a difficult road might be taken. The question had been restricted to cholera quarantine because the special discussion would be of great value as regards the general subject.

Dr. OSER, one of the referees, then read a long article, of which the following is a summary:

This question, of such intense interest to medical men, has a vast literature of hypothesis, plans for prevention and cure, which cannot stand the criticism of scientific investigation.

As regards the most important question, the influence of commerce, men say that further discussion is unnecessary, and that quarantine and restrictive measures seem useless. Most writers agree as to the vast influence of trade in spreading cholera, only Dr. Bryden, on the ground of Indian observations, coming to different conclusions. The monsoon theory must, among other things, explain how the great epidemic of 1818 travelled from Madras down to Bombay against a prevailing monsoon, why it spread over the whole country without regard to the direction of the winds, and, still further, why in 1865 it spread in every direction from Alexandria into Europe.

Cholera only travels along lines of trade, always passing inwardly from the harbors; and this is one of the best-established facts in our knowledge of the

disease. Since it is not found native outside of India, complete abolition of commerce would be absolute protection against cholera. But trade is not and cannot be suppressed: therefore quarantine cannot be universally protective. Its duration is too short, so that, after passing through quarantine and departing, cholera often breaks out among the passengers. It is even more difficult to restrict in thickly populated states with much internal commerce. Cholera has a preference for the land-routes. A ship offers no favorable ground for the development of a cholera, and ship-epidemics are very rare. Again, quarantine stations are like prisons, which every traveller regards with terror. The result of quarantine, stated by its warmest defendant, amounts to but very little. Witness Greece and America. Though the fact exists that where quarantine is in force cholera is diminished, the speaker asked if there was any proof of a causal relation of both forces. England has suffered less than almost any other country, yet she has never carried out a rigorous quarantine, in the idea that through it alone protection could be obtained. Countries with limited trade by the sea may be able to protect themselves through a strenuous quarantine, but its universal protective influence cannot be deduced from the facts yet presented. We know that commerce sustains an enormous damage, amounting to millions yearly. The Constantinople conference declares it much less than industry and trade suffer through an epidemic of cholera. An exchange of a cholera epidemic for a commercial trouble would be satisfactory to all, but now we put up with both.

The speaker advises, then, an international commission of tried and trusted experts, who shall, without fear or favor, make the most rigid and minute investigations into these questions,—the lines of travel of cholera,—and accurate statistics. The abolition of quarantine without any substitute cannot be expected. Again, what good does it do between two sea-ports where land-communication is carried on? Especial attention must be paid to the hygiene of trade by land and sea. Let us find no fault with the Mecca pilgrims, when we have our Lourdes and Kiew. A vigorous official supervision of all means of transportation, attention to the hygiene of sea-ports and places of entrance of cholera over railroads, are yet wanting. When first the help of all these regulations is obtained, when hygiene lends its aid in the shape of good drainage and good water-supply, and when the state finds that the practical meaning of medicine lies in hygiene, then epidemic diseases will be shut into narrow quarters, and a great obstacle will be presented to their onward progress.

Dr. SCHNEIDER, of Java, considered commerce the etiological force, to which he attributed the often slow progress of cholera and the time occupied in finding its way to America.

Dr. EULENBERG, of Berlin, having watched the march of an epidemic, was opposed to quarantine.

HASSAN EFFENDI said that cholera, commonly epidemic, was endemic on the banks of the Ganges. Travellers from India bring with them the implanted virus, which, under the proper circumstances, develops. Only thus could he explain

the fact of the advent of cholera into Europe since 1868, while no case has occurred in Egypt; further, the epidemic of 1865 was coincident with the arrival of pilgrims from India.

Dr. CARMINHOA, of Brazil, was opposed to quarantine, because it could not prevent the introduction of the disease.

Dr. WITLACIL thought the transmission of cholera was accepted by most physicians.

Dr. LUDWIG GRÖSZ, of Buda-Pesth, declared for the abolition of quarantine, except in the case of the cattle-murrian.

Dr. GIACICH, of Fiume, favored quarantine on the same grounds as compulsory vaccination.

Dr. GREGORIC, of Belgrade, declared himself opposed to quarantine, because it was impossible to carry it out effectually, and because he believed in *the spontaneous development of this species of malarial disease*, and could bring forward cases of its occurrence in completely isolated districts.

FIFTH SESSION.

The fifth session was held September 3, at four o'clock P.M.

Dr. SCHNEIDER was opposed to land-quarantine, and considered the wind a factor in the diffusion of cholera.

Dr. WITLACIL said that a majority seemed opposed to land-quarantine. Two have favored it. Theoretically it is quite right, when one reasons that, as cholera is a transmissible disease, it is well to hinder that transmission and isolate every place where it appears. The facts are that quarantine does not prevent the spread of the disease, is not suited to European circumstances, is too disadvantageous to commerce, and should be abolished. The conditions of Egypt are not like our own. We must deal with our own conditions. Land-quarantine is an idea which it is absolutely impossible to carry out.

The President, Dr. GUNTHER, gave the expressed opinions of the cholera commission of Germany: a complete seclusion on land is impossible, and therefore restrictive regulations are without success.

Dr. HUMANN thought that if international regulations for quarantine on the sea were to be established, a glance at facts already gathered by experience of various countries would be of use. Norway is a country where only sea-quarantine can come into application, but where also, from the circumstances of a wide-spread commerce, a rich experience can be obtained with regard to quarantine.

In the years 1865 and 1867 there were no cases of cholera in Norway. In 1866 there were only 80 cases, of which 50 died. In this year, when cholera was abroad in Europe, no less than 3128 ships, from places where cholera was raging, came to Norway, of which 28 brought persons dead or sick with genuine cholera, and 25 brought suspected cases of cholera. The rules were—medical inspection of every ship which came from a cholera locality, and isolation of completely developed, as well as of suspected, cases.

The ships were brought to a certain locality and

purified, and the passengers at the proper time sent on shore, or the sick kept isolated on board until the cases were ended. Not one ship imported the disease on shore. The cases which did occur were imported. A ship from a non-suspected port having on board a case of cholera-diarrhœa, the disease extended to others of the crew, and to the ships near at hand in the harbor. Another source was a ship not thoroughly inspected. The third set of cases were brought into the mainland from a near district in Sweden; but no wide diffusion of cholera occurred from any. The cases were isolated, buildings thoroughly disinfected, and the system proved to be a protection against the disease.

Dr. GIACICH, of Fiume, declared that a bad system of sea-quarantine would get as many enemies as the land-system. It originated with Maria Theresa, and lasted forty days for each ship, whence the name. We do not know the incubation-time of cholera. Hence we must consider the length of time the voyage has continued, whether the ship is heavy, and what the cargo, whence she comes, and how many men she has on board,—since with a great cargo and numerous passengers the spreading of the disease is to be feared. The speaker believed that cholera diffused itself through the air, as well as from persons and clothing.

Prof. CROCCQ, of Brussels, was an opponent of quarantine, because it is impossible to carry it out practically, and also because cholera has raged no more severely where quarantine was carelessly or not at all carried out than in countries where it was rigorously executed. It should be applied only to ships with the disease coming to ports where it does not exist.

Dr. SCHERZER, on the grounds of a very large private and official experience, considered quarantine not only insufficient, but also inhuman,—indeed, horrible. As the Chinese wall fails to keep out the contagion of European civilization, so will a complete net-work of lazarettos fail to keep cholera out of the country. By the great extension of the means of trade, quarantine is made an absurdity. A traveller embarking at Trieste for the Orient must delay fifteen days in Italy, Syria eleven days, and Constantinople eleven days more, in quarantine. In conclusion, the speaker felt obliged to demand the removal of quarantine in its present form.

Prof. CASTIGLIONE, of Rome, said that the idea that cholera attacked only filthy localities and people was not correct, for in 1854 over 5000 people were carried off in Brescia, the cleanest city of Lombardy, while the wretched Jews' Quarter of Rome escaped. The speaker was in favor of sea-quarantine, not as affording absolute protection, but because in certain cases it could be useful.

Dr. WITLACIL, in a review of the debate, remarked that all had spoken against sea-quarantine as at present conducted, though all believed in its application to a ship with the disease coming to a country at that time free.

The results of the votes then taken were not given until Saturday. The following resolutions were passed by large majorities:

1. Land- and sea-quarantine is to be abolished.

2. Sea-quarantine is to be temporarily continued, however.

3. An international commission for the study of the agencies which spread cholera, and for eliminating them from commerce, as well as for finding rules which shall give greater protection than the present ones, is to be appointed.

SIXTH SESSION.

The sixth session was held on Thursday, September 4. President, Dr. EULENBERG, of Berlin, assisted by Dr. HAMM and Dr. INNHAUSER, with Prof. BOHM as referee. The question was, "The Sanitary Management of a City, with Reference to Drainage and Water-supply."

Dr. BOHM gave the conclusions of the referees, as follows:

1. The purification and improvement of the city must be pointed out as an unavoidable demand from a sanitary point of view, and the study of the question is of the utmost importance.

2. For the conveyance of water to and from the houses, as well as channels for the surplus water, canalization is necessary in every city, and must be established in accord with hygienic demands.

3. The refuse of the inhabitants is to be conveyed away through rational means, in accordance with hygienic laws and the interests of the people.

4. In every case the circumstances of the city, the water-supply, the cost of engineering and management, the capability of paying, etc., must be all regarded.

5. As a rule, a good system in accord with hygienic demands can be made in a cheap and workable way.

6. The carrying off at least partially of fecal material, and of the greater part of the urine, is necessary.

7. Cities ought to engage in the discussion of these questions concerning the purification of the state and city, with the assistance of experts.

The discussion of these points briefly epitomized above was participated in by a number of gentlemen interested in the subject. The previous questions of the Congress seemed of so much consequence that I reported them more fully. Of this I can only say that Dr. ARADI, Prof. WARLOMONT, Dr. FOLWARCZNY, Dr. GRUBER, Dr. INNHAUSER, and others spoke, and in the afternoon session (No. 7 of the Congress) Dr. WITLACIL, Dr. EIGENBRODT, Major NIGRAS, and others.

These points mentioned above were officially adopted by the Congress by a vote of 156 out of 181.

EIGHTH SESSION.

The eighth session was held on Friday, September 5. President, Dr. ABDULLAH BEY, assisted by Dr. CARMINHOA and Dr. WITLACIL, with Dr. JOHANN SCHNITZLER for referee. The question was, "The general subject of Quarantine."

Dr. SCHNITZLER proposed—(1) That the present method of quarantine is untenable on many grounds, especially because it cannot be carried out sufficiently to protect against all epidemic

diseases, and is in daily conflict with commerce. (2) A series of quarantine rules must be provisionally retained. (3) The plan for the moment should be the calling of a permanent commission for the study of epidemic diseases, having in view the eventual establishment of international regulations.

Prof. CARMINHOA proposed—(1) International measures for the purification of the Ganges, the Nile, the Danube, and the American rivers emptying into the Gulf of Mexico. (2) Purification of places according to hygienic laws. (3) Quarantine for such ships only as come from suspected ports, or have disease on board which has broken out within fifteen days from the departure on the voyage.

Dr. WALLNER, of Trieste, Dr. BENEDICT, Dr. AUSPITZ, Dr. SPAETH, and Dr. KAPOSI, also spoke, and the Congress finally declared itself as follows:

Quarantine is to be restricted to the time necessary for the examination and disinfection of ships, crews, and passengers. If there be no sickness on board after disinfection, a free passage to be allowed. If sick persons be found, these are to be isolated, and the ship disinfected, with free passage afterwards.

Against yellow fever and the plague the previous rules remain in force.

The question pressing for solution now is how to change the existing quarantine laws in accordance with the points of view previously set forth.

A permanent commission on contagious diseases is to be appointed for a thorough study of the question in all its bearings, which can bring forward definite grounds for a universal sanitary code of laws.

NINTH SESSION.

The ninth session was held on Friday, September 5. President, Prof. RATTI, Rome; Vice-Presidents, Dr. CAPSA and Prof. BERNATZIK; Prof. BERNATZIK, Prof. SCHROFF, sen., and Dr. SCHROFF, jun., were the referees. The subject was, "The Establishment of an International Pharmacopœia."

On this point the committee, among other questions, asked, Is it possible to take one of the existing pharmacopœias for universal use? If this be declared impossible, can it be expected that a pharmacopœia written expressly for international use can serve the purposes of the various countries satisfactorily, as regards the choice, composition, and peculiarities of the remedies? And again, Can the object which is arrived at in the establishment of an international pharmacopœia be obtained in no other way, and what regulations must be established for the purpose?

The resolutions were declared on Saturday, and read as follows:

1. The Congress recognizes the need of an international pharmacopœia. This must contain the most essential and best-known remedies, the most necessary excipients and corrigents, with a precise description of their qualities and method of preparation; the Latin language to be used in the text, and in the relations of the components the decimal system.

2. The Congress wishes that for the future the metrical system be used in prescribing.

3. The Congress intrusts to the president of the Fourth Congress the organization of an international commission for the revision of the pharmacopœia.

TENTH SESSION.

The tenth session was held on September 5, at four o'clock P.M. President, Dr. RECLAM, of Leipsic, assisted by Dr. HUBNER, of St. Petersburg, and Dr. SCHNELLER. Referees, Prof. BENEDICT and Dr. WILLIAM SCHLESINGER. The question was, "The Social Standing of Physicians."

The questions submitted were as follows:

1. Is the practice of medicine to be free, and in what is this freedom to consist?

2. Is this freedom worth wishing for, and under what regulations is it to be commended?

3. Are there means for checking quackery, and, if so, what?

4. Are there cases where any physician can be called upon to give medical aid?

5. Is the official establishment of a medical tax advisable?

6. How can medical interest be best preserved?

Dr. WILLIAM SCHLESINGER made a long speech on the question, followed by Prof. BENEDICT, Dr. ABDULLAH BEY, Prof. CROCO, Dr. MARCOWIC, of Bucharest, Dr. MEDOVICH, of Belgrade, and others. The Congress declared itself in favor of the first point, but only on condition of similar antecedent and professional education and similar evidence in proof of authority to practise, and emphatically opposed No. 4.

FINAL SESSION.

The final session occurred on Saturday, with Prof. ROKITANSKY in the chair. Speeches were made by Prof. MAZZON, of Kiev, Dr. VAN DER LOO, and Major NIGRAS, who had spoken acceptably before, and made an earnest plea for Philadelphia as the next place of meeting.

Prof. ROKITANSKY gave a short review of the progress of the discussions, and declared the sessions closed.

The Fourth Congress will assemble at Brussels. During the sittings of the Congress a small number of experts in mental and nervous diseases have held daily sessions. Such men as Prof. MEYNERT and Prof. LEIDESDORF, of Vienna, Dr. NOSTER, of Marburg, Dr. WISLOCKY, and others, have met and discussed various points. The question, How can the insane be restored to sanity in the quickest way? was discussed at the first meetings. To Prof. MEYNERT was referred the question, How can we attain a natural method of treatment for mental debility?

A number of monographs and articles on various subjects were distributed among the delegates, or handed to the secretary for future publication.

In connection with the Congress there have been gatherings at the hotels in the evening, various receptions, a banquet at the "Kur-Saal" on Sunday evening, excursions to the new water-works of the city, and a trip by rail over the wonderful Söm-

mering road. Over eight hundred delegates have registered. Among them appears the name Baron Dr. SEYDEWITZ, representing the United States,—a gentleman who informed me that we have no good physicians in America (now that he has left, probably). This is another case of the unaccountable yet splendid mismanagement which has attached to everything we have tried to do here. Almost the only speaker we had at the Congress has been a perpetual disgrace since the Exposition opened, by reason of his riotous living.

The doings of the Congress have come in for a considerable share of criticism. Some articles have handled it without gloves. It is very evident that some questions thought to be already settled are to come up again. If I were to express a seeming sentiment among some of the more prominent members, I should regard it as not, upon the whole, a very satisfactory gathering.

GRAFTING THE SKIN OF A WHITE MAN UPON A NEGRO.

BY G. TROUP MAXWELL, M.D.,

New Castle, Delaware.

I WAS called in February, 1872, to see James Pearce, a negro, who had been shot in the face by the accidental discharge of a gun. The gun was loaded with bird-shot, and, as Pearce was only a few feet from its muzzle, the charge passed through the left cheek almost in as compact a mass as a solid ball, entering just at the outer border of the orbicularis muscle. The shot made a wide and deep furrow through the soft parts, completely severed the masseter muscle in its middle, and escaped at the posterior border of the ramus of the inferior maxillary bone, just below the lobule of the ear. The buccal mucous membrane and the bone were uninjured; but the wound involved all the structures lying exteriorly to them, and, as by retraction of the severed tissues the lateral dimension of the wound was considerably increased, it presented a horrible appearance, the ghastliness of which was increased by the charred and blackened effect of the burning powder.

An effort was made to contract the limits of the wound as much as possible, by approximating its sides as closely as could be done with adhesive strips and bandages; but, notwithstanding all the care that was taken, the sloughing was so extensive that there resulted a deep, disfiguring wound, of irregular shape, and covering nearly the whole left cheek.

To expedite the healing process, and to prevent, as far as possible, the disfigurement of an extensive cicatrix, I proposed to graft skin into the wound as soon as it presented a healthy granulating surface. This proposition having been assented to, I performed that operation in March, about four weeks after the injury was received.

Whilst making preparations for the operation, the idea of grafting the skin of a white man upon a

negro occurred to me; and, having obtained the consent of my patient to the procedure, I clipped from my own left forearm a piece of skin about the size of a dime, for the purpose. I also took a piece from his forearm, intending to graft both white and black skin.

These pieces of skin were divided into small fragments about the size of canary-seeds, and four of each kind were carefully inserted into the surface of the wound.

On the tenth day, the bandages and strips of plaster which held the grafts *in situ* were removed, and six of the eight grafts were discovered to possess vitality and to encourage the hope of success.

Unfortunately, that day, after the dressings had been changed, my patient got on a "spree," and, whilst intoxicated, destroyed four of the grafts. Happily for the success of my experiment, of the remaining two, one was white. These grafts grew finely, extending themselves in all directions, and assisted materially in closing the wound, which was quickly done.

Besides the wish to heal the wound as speedily as possible and with the slightest amount of cicatricial contraction, considerable interest was felt in the result of the experiment—which, so far as I am informed, had never been done before—of grafting the skin of a white person upon a negro. It was a source of gratification, therefore, to witness the growth of the white graft, and I watched its progress with peculiar pleasure. From the size of a canary-seed, it increased to the extent of about a half-inch in its greatest dimensions, and was of irregular form, with narrow points extending into the surrounding black surface.

Meeting Pearce on the road after the wound had healed, I readily distinguished the white patch in the side of his face, twenty to thirty yards distant. Upon examination at that time, dark-colored lines, forming a net-work in the white skin and giving it a purplish tinge, were discerned. These, I supposed, were blood-vessels. These vessels increased in size and number, producing a corresponding deepening of the color of the patch, until by the end of the third month the whole surface of the wound was of a uniform blackness. The white skin had lost its distinguishing characteristics.

Does not this experiment prove that the coloring-matter of the skin, its pigment, which varies in quantity in individuals as well as in races, is due to cells which are developed in the liquor sanguinis, and not to any peculiarity in the cells of the skin itself?

FATAL PERITONITIS FROM RUPTURE OF A PELVIC ABSCESS.

BY A. K. MINICH, M.D.

MRS. H., German, aged 30, mother of three children, after a few days of slight suffering from pain in the lower portion of the abdomen, and for which her husband administered Hamburg tea (the inevitable remedy among Germans), was suddenly attacked with very violent pain in the hypo-

gastric region. As I was not at home, another physician prescribed. About six hours later I found her in intense agony, abdomen tympanitic and painful to the touch, hurried respiration, and rapid wiry pulse. Death followed in about twenty hours.

Autopsy made one day after death, by Dr. Haynes and myself, revealed the following:

Peritoneum injected, showing everywhere traces of inflammatory change. Pus and liquid feces low in peritoneal sac. The empty sac of a large abscess was found upon the upper left side of the uterus, the summit and side of which were partially attached to the colon of the corresponding side.

Treatment after the rupture of the abscess was, of course, unavailing. But had the abscess been discovered a few days earlier and a bistoury passed through the uterine wall into it, allowing the pus to escape via the uterine cavity and vagina, there is no doubt that she *might* have been saved.

2228 NORTH FRONT STREET, PHILA.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY OF PENNSYLVANIA.

SERVICE OF DR. LOUIS A. DUHRING.

Reported by Dr. ARTHUR VAN HARLINGEN.

DERMATO-SYPHILIS.

THIS man presents an eruption consisting of some half-dozen ulcers, grouped so as to form a semi-circular patch about three inches in diameter, on the arm, midway between the elbow and the axilla.

The appearance of these ulcers is characteristic of the disease: they are crescentic, vary in size from that of a pea to that of a large bean, have a deep, punched-out appearance, and are covered with a sanious, yellowish-gray exudation.

The patient states that he has never had chancre or other symptom of syphilis. He had an attack of gonorrhoea many years back.

About one year ago he noticed a small nodule or tubercle on his arm at the seat of the present eruption, followed shortly after by several others of the same nature, which eventually broke down and formed the ulcers for which he now seeks relief. These ulcers increased in size with remarkable slowness.

In spite of the total absence of any history of a primary lesion or of any of the earlier symptoms of syphilis, there can be no doubt that the sores are due to syphilis and nothing else. We need nothing more than these appearances to make our diagnosis. Should we in these cases rely on always obtaining a history of syphilis, we should often be very much at fault with our diagnosis.

The exceedingly slow course which the disease has pursued in the present case would almost lead us to believe that the patient had been under a course of antisymphilitic treatment; but he assures us to the contrary. We may therefore conclude this to be syphilis of a mild type, entitled to a very favorable prognosis. The patient will take the following:

R Potassii iodidi, ʒv ʒj;

Tr. cinchonæ comp., fʒiv.

Sig.—One teaspoonful three times a day after meals.

Locally the ulcers are to be dressed with unguent. zinci oxid. and kept perfectly clean. Under this treatment we may expect rapid improvement.

[The patient appeared before the class a week later, much improved. The ulcers had lost their previously unhealthy character, and were granulating rapidly.—A. V. H.]

HEREDITARY INFANTILE SYPHILIS.

The history of this little patient is as follows. The mother has never had any syphilitic disease, but the father's record is more than doubtful in this respect, though nothing is positively known. Up to four years ago they had four healthy children; then the woman suffered two successive miscarriages. When this child was born it seemed weak and small, but to all appearance healthy, and no sign of disease manifested itself until it reached the age of four weeks. At that time it began to show unmistakable signs of syphilitic disease.

A "scurf," it is stated, appeared over the entire surface of the body, which peeled off in dry scales. Shortly after "sores" broke out on the head and feet, and the skin about the genitals became excoriated. Meanwhile the child's appetite failed, and it became weak and emaciated to the last degree.

Its condition to-day is decidedly better than when it first came under treatment a month ago, though still characteristic of hereditary infantile syphilis. The skin is sallow and wrinkled, the eyes are hollow, and the skin of the face has a dead, waxy look, with a drawn expression about the mouth. The whole aspect of the child, in fact, resembles that of premature old age and decrepitude.

In addition to these signs of general malnutrition, we have more positive evidences of disease. A scattered papular eruption exists over the body and limbs; there are also pustules about the soles of the feet, desquamation of the skin on the palms of the hands, and one or two small abscesses on the fingers. About the genitals there are, you will observe, a number of well-marked mucous patches. Considerable stuffing up of the nasal passages exists, but as yet there is no discharge. A thin, yellowish fluid oozes from one ear.

A case like this demands prompt and energetic treatment and yet great caution; for a very slight matter will often be sufficient to upset the balance of so precarious an existence, and cause the physician to be unjustly blamed.

The treatment adopted in this case has been as follows. At first baths containing corrosive sublimate were directed. Ten grains of the sublimate were to be dissolved in a wash-tub of water sufficiently warm, so that the little patient might not get a chill in the bath. In this bath the infant was to be immersed for ten or fifteen minutes, care being taken that none of the solution should be splashed into its mouth or eyes.

In many cases this treatment is sufficient. It was continued for about a week in this instance, and then, as the mother became apprehensive lest the child should die in one of the baths, they were discontinued, and another plan was adopted. Inunctions were directed of the following:

R Unguent. hydrarg.,
Adipis, aa ʒss. M.

Of this ointment a piece the size of a pea was to be rubbed well into the skin of the abdomen and other parts of the body alternately, care being taken not to rub too frequently in any one locality, and to avoid abrasions.

Under the use of these inunctions decided improvement has taken place: the child sleeps well, his appetite is better, and his general appearance is much improved. The prognosis, however, can scarcely be called favorable,—the appearance of several large abscesses on different parts of the body showing such a tendency to disintegration of tissues as renders the prospect of recovery slight.

Before leaving the case, let me call your attention to the peculiar whining cry which the child utters from time to time, and which is to a certain extent characteristic.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. H. C. WOOD, JR.

Reported by Dr. J. WM. WHITE.

TYPHOID FEVER—COLD PACKS—RELAPSE—RECOVERY.

HANNAH McF., an unmarried woman, æt. 22, entered the medical wards of the Philadelphia Hospital, December 22, 1872, after having been sick for about three weeks. At the time of admission her pulse was 126, rapid and feeble; respiration 26 and labored; tongue heavily coated and fissured; abdomen covered with rose-colored spots and greatly distended; temperature 104°; bowels opened from three to five times daily, the passages being thin, offensive, and brownish. The patient was very drowsy, slept most of the time, and was wakened with difficulty. She was put on a diet of milk, beef-tea, and whisky, with small doses of laudanum and quinia; her stools soon became less frequent and of a better color, but with this exception there was no change in her condition until the 26th. Her temperature then reaching 104½°, she was placed in a wet pack at 75° twice during the day, and was allowed to remain there for two hours each time. This lowered her temperature 1.5°, improved her general condition, and lessened the severity of her symptoms. She expressed herself as feeling greatly relieved, and said that packing was very agreeable to her. On the 27th and 28th the packs were repeated, but on the latter day she had a profuse uterine hemorrhage, which was only controlled by the tampon, and the packing was therefore discontinued until the 31st. It was then recommenced, but was again stopped on January 2. During this time she suffered somewhat from pain in the chest, with a troublesome cough, and crepitant râles with dullness on percussion were found. Squills were given as an expectorant, turpentine stupes were applied, and the cough and pain disappeared. Until the 28th she was taking an ounce of milk-punch—equal parts of milk and whisky—every two hours, but after the occurrence of hemorrhage this amount was doubled. Her general condition from day to day may be tabulated as follows:

Date.	Packs.	Pulse.	Resp.	Temp.
Dec. 26, A.M.	2	118	27	104½°
P.M.		110	27	103½°
27, A.M.	2	118	27	104°
P.M.		126	29	104½°
28, A.M.	3	126	36	105°
P.M.		114	30	102½°
29, A.M.	0	116	39	104½°
P.M.		126	32	104°
30, A.M.	0	116	30	102°
P.M.		112	30	101°
31, A.M.	2	110	36	103°
6 P.M.		100	27	102°
Jan. 1, A.M.		100	27	100½°
2, "		94	27	98½°
3, "		94	27	99½°
4, "		94	24	99½°
5, "		94	25	99½°

From this date up to the 15th she steadily improved in every particular. On the 15th she had some pains in her bones, and was chilly and restless. On the morning of the 16th she got up and made her bed, having been out of it only once before, and then having

been assisted with great care to sit up a little while. Shortly after going to bed again on the 16th she was seized with a high fever, the pulse became thready and so rapid that it could not be counted, her respirations rose to 50, and her temperature to 105°. She was given two ounces of whisky hourly during the day, and one ounce at night whenever she was awake. A turpentine and fever mixture was also administered. She, however, grew rapidly worse, and became exhausted, stupid, and finally delirious. Packing was again resorted to. She was wrapped in a sheet wet with water at 55°, and in three-quarters of an hour her temperature fell to 103°, but an hour later it had gone back to 105°. After an interval of a couple of hours she was packed with a sheet at 32°. She made no complaint, and did not seem to find it unpleasant, but her temperature was reduced only one-third of a degree. This was late in the afternoon. The following morning, January 17, her temperature was still 105°, but her respirations had fallen to 30, and her pulse was only 125, and much improved under the whisky which had been given. About ten o'clock she was wrapped in a sheet at 32°, and kept there for an hour and a quarter, and this was repeated for a shorter time in the afternoon; but on neither occasion was there any distinct fall of temperature. She took an ounce of whisky each hour during the day.

18th.—Temperature 104°; general condition much better than at any time since the relapse. The packing was repeated, and whisky given as before.

19th.—Temperature 102.5°; packing discontinued; whisky given in smaller doses. Improvement was uninterrupted until the 22d, when there was an exacerbation of fever, the pulse rose to 168, and coarse, subcrepitant, sibilant, and creaking râles developed themselves posteriorly in both lungs. She was placed on muriate of ammonia, counter-irritation was freely applied, and she again grew better, until on January 28 her respirations were 30, her pulse was 118, and she was regaining her strength.

She now progressed steadily to complete recovery, and early in March was able to leave the hospital.

PHILADELPHIA HOSPITAL.

Reported by JOHN M. KEATING, M.D., Resident Physician.

CASE OF EPILEPTIC CONVULSIONS AND HEMIPLEGIA IN THE ADULT, APPARENTLY REFLEX AND DUE TO LUMBRICI.

A CASE which recently came under my notice in the medical ward of the Philadelphia Hospital, for the permission to report which I am indebted to Dr. J. L. Ludlow, Visiting Physician, may be of interest to those of your readers who are studying the subject of reflex action.

On the night of July 14, I was called to see a man who had been brought to the hospital a few moments before by a policeman. The officer stated that he had picked him up on the street unable to speak, and that therefore he could get no history from him. When seen by me he was just recovering consciousness, unable to articulate, but he evidently understood all I asked, as he shook his head yes or no to all my questions. His pulse was 90 and strong, and the heart-sounds were loud and normal. He was breathing heavily. The entire right side of his body, except the face, was paralyzed. The paralysis was both of motion and of sensation. He was ordered cut cups to the back of the neck, and about six or seven ounces of blood were drawn. The tincture of aconite root was given in three-drop doses, repeated as indicated, cold cloths ordered to be applied continually to his head, a drop of croton oil administered, and I left him for the night.

Next morning the pulse was beating 75. The oil had had no effect, and a dose of salts was now given. At 5 P.M. he could articulate a few words. He had vomited much during the morning, and the continued nausea was supposed to denote a complication at the base of the brain. Warm water had been freely administered, and he at last with much difficulty threw up a large lumbricus, after complaining of a continued pain in the epigastrium. The temperature of both limbs was the same; the pupils were normal and of equal size. Sensation was returning gradually. He was now able to speak much better.

July 16.—Sensation returning to right shoulder. He is to-day able to speak well. He says he is 33 years old, has never had syphilis, and was *never before paralyzed*. The improvement continued; cathartics were used for several days. Two days afterwards he was able to walk with the aid of a cane. About the fourth day from the commencement he was seized with a violent pain in the epigastrium similar to that from which he suffered when he vomited the worm several days before. This time he vomited nothing. At the end of the first week he had an attack resembling an epileptic convulsion, with marked spasmodic contraction of limbs, which after return to consciousness still affected the right side. There was once more entire paralysis of motion and sensation. After the attack he was cut-cupped, and a purgative ordered. This was followed by the passage of a large worm which was dead when discharged. In two days he was able to walk around the ward with the aid of a stick, sensation completely returned, and motion enough so as to give him almost complete control of his arm and partially of his leg. Anthelmintics were thought to be indicated, and oil of chenopodium was ordered in five-drop doses, followed by castor oil, but no worms made their appearance. Santonin was substituted, with like result. He had several slight convulsions, with but little increase in the paralysis. Bromide of potassium was prescribed, and under it and tonics he rapidly improved until August 11, when he was discharged at his own request, with scarcely any paralysis, and with but little loss of power remaining. These attacks were his first *epileptic fits*.

Upon inquiry I learn the following history previous to his admission to this hospital, through the kindness of Dr. David Maich, Jr. P. S. arrived in Philadelphia on the Baltimore boat, Saturday night (June 21, 1873). Sunday morning, after eating heartily, he started to walk to the country (the thermometer stood at 83° in the shade). The last thing he remembered was crossing the stone bridge on the Germantown Road. He had taken no stimulating drink, as he says he is a temperate man. He was brought to the Episcopal Hospital by a policeman at 11.30 A.M. He was unconscious when admitted. Temperature 98°; respiration slow, labored; no convulsions; pupils were normal. He was treated by ice to head and warmth to feet, whisky, etc. When he rallied he complained of headache.

The next morning he was placed upon twenty grains of bromide of potassium every six hours, and was discharged well on July 14. As the man's case was of much interest, I wished to follow up his history. But he had not reached the destination for which he started when he left us by the 22d of September, as I was informed by the Superintendent of the Howard Home for Disabled Soldiers. It appears that the attacks which brought him to the two hospitals were entirely dissimilar. In the second he was affected with paralysis, the recurrence of which was followed by the passage per anum of a dead worm; and the rapid recovery which enabled him to walk about the hospital within three or four days from the seizure denoted anything but a distinct brain-lesion.

TRANSLATIONS.

RESEARCHES UPON THE PHYSIOLOGICAL EFFECTS PRODUCED BY THE ABSORPTION OF THE SALTS OF SILVER.

By PROF. CHARLES ROUGET. Translated from the *Archives de Physiologie* for July, 1873.

BY FRANK WOODBURY, M.D.

THE experiments heretofore made by a number of observers to ascertain the physiological action of the salts of silver, M. Rouget believes, have yielded incorrect results, because in all of them the agent has been injected into the veins; thus producing accidents, which, although often directly due to the process employed, have been all attributed to the toxic agent.

In the experiments detailed by M. Rouget, on the contrary, this process has been avoided, and the argentic salt has been introduced into the organism by absorption; either from the cutaneous surface or by hypodermic injection into the cellular tissue, into the subcutaneous lymphatic sacs of frogs, or, exceptionally, into the peritoneal cavity. By this means the complications arising from the abrupt introduction of a foreign element into the blood are avoided, and the substance reaches the nutritious fluid slowly and a little at a time by absorption, as in the normal physiological condition.

Considering the question as still undecided, he has experimented upon animals from all the classes of the vertebrata and several orders of the mammifera, even descending to some of the invertebrata, insects, and crustaceans. The experiments upon the amphibia, in the larva and adult states, have been very numerous; the others have always been repeated upon several animals of the same species.

Solutions of the strength of $\frac{1}{100}$ to $\frac{1}{1000}$ of the argentic nitrate were first used; but later he substituted the solution of the chloride of silver or of the nitrate, dissolved in the hyposulphite of soda. The phenomena in batrachians produced by the introduction of the silver nitrate by absorption, approach closely in their appearance to those presented by frogs paralyzed by a feeble dose of curare: voluntary motion is suspended; respiration stops; reflex movements, after having persisted some time, gradually disappear; the circulation alone continues, and is performed with regularity from one-half to two hours. These phenomena of argyric intoxication in batrachians seem to bear no relation to those reported of dogs in whose veins the silver salts have been injected.

After relating a number of experiments, he deduces these general results:

In all the experiments the salts of silver having been introduced by absorption, intoxication occurs later than following injection into the veins.

He has not had a single case of *instantaneous* death, even in a dog in which sixty centigrammes of hyposulphite of silver were injected into the cellular tissue.

Moreover, two centigrammes of the same salt, introduced in the same way, were tolerated by a dog who showed no evil effects whatever, while the same dose injected into a dog's veins by MM. Rabuteau and Mourier produced fatal intoxication in twenty minutes.

At present, two opinions regarding the physiological action of the silver salts seem to exist: the one attributing the phenomena observed to an action on the nervous system (Orfila, Charcot, and Ball); the other, on the contrary, considering them as the result of a chemical change in the blood, producing the bronchial hypersecretion, and, in the sudden deaths, causing arrest of the heart's action by direct poisoning of its muscular fibres (Krahmer, Rabuteau, and Mourier).

In all the animals, vertebrata and invertebrata, the first phenomena declaring the poisoning are, without any exception, the troubles in the functions of the nervous and muscular systems of animal life, from feebleness or torpor to those of the most grave character, complete loss of voluntary motion, convulsions, contractions, and paralysis.

In the second place, appearing with more or less promptitude after the preceding, occur troubles of breathing: a function whose regular accomplishment depends not only upon physical and chemical conditions, but also upon mechanical ones governed by certain nerves and muscles belonging both to animal and organic life. One of the least contestable of the results in these new experiments is that these troubles of respiration, which are always present, are only in two species of carnivora, the dog and the cat, accompanied by pulmonary lesions and bronchial hypersecretion (to explain which others have suggested a chemical change of the blood). In all the other animals the troubles only exist in the mechanical portion of the respiratory apparatus, that is, the muscular and nervous systems, and the lungs are found after death healthy but contracted; a state which declares that in the muscles and nerves of the pulmonary parenchyma there exist troubles analogous to those in the external mechanical portion (convulsions, spasms, and permanent contractions). The special phenomena of hypersecretion, œdema and pulmonary congestion, only observed so far in dogs and cats, can equally be considered as a consequence of the action of the toxic agent upon the nervous system. When observing this access of convulsive suffocation, followed by the expulsion of flakes of bronchial foam, it is impossible not to be struck with the analogy which all this bears to the onset of asthma, especially to *asystole*, which terminates in asphyxia and death. The pulmonary lesions, œdema and congestion, seen in dogs thus poisoned, are the same as those found in asthmatic subjects, especially where death occurs from *asystole*. Besides, in all the lung-breathing vertebrata poisoned by the silver salts where there were no pulmonary lesions, we have always found immediately after death the lungs retracted and much less voluminous than usual. This results from contraction of the bronchial muscular fibres, coincident with that of the external respiratory muscles; which is considered by Cullen to be the immediate cause of asthma.

All the experiments prove that the vaso-motor system is the last to resist the toxic effects of this agent. By exclusion the troubles of respiration are explained by a toxic action upon the respiratory centres in the medulla itself, which governs not only the spinal nerves of the external respiratory muscles, but also the nerves of the bronchial muscles through the pneumogastrics. At a more advanced stage the centres of origin of the vaso-motor nerves of the lungs, confounded partly with those of the pneumogastric in the immediate neighborhood of these ganglia, are able, under the paralyzing influence of the toxic agent, to determine in the lung the phenomena of congestion and hypersecretion; resembling that seen in the liver and kidneys following mechanical irritation of the floor of the fourth ventricle. This hypothesis seems more in harmony with the observed facts than the one which attributes the pulmonary troubles to reflex action (Charcot and Ball).

In the inferior vertebrata, where a comparatively large dose acts more slowly than in the mammifera, and even in the mammifera if the dose be feeble, we are able to notice an increase in the excitability of the reflex centres. In the fish, batrachians, and saurians, one of the first evidences of the toxic effect is the substitution of violent convulsions for voluntary efforts. These convulsive movements persist, even augment in intensity, when voluntary motion is suspended; and, even after the

arrest of the circulation, external excitation, by shaking or even contact, produces reflex convulsions. When the respiration has ceased, mechanical excitation provokes the return of a few inspiratory movements with the convulsions. These experiments, whether by nitrate or hyposulphite of silver, show great analogy to the tetanus produced by strychnia-poisoning.

The assimilation of the therapeutic action of the nitrate of silver to that of strychnia, the property common to these two agents of setting in action the excitomotor power of the medulla, which Charcot had previously deduced from clinical observations, is therefore proved and corroborated by physiological experimentation.

The specific action upon the cardiac muscular fibre, causing sudden arrest of its action, which has been asserted by some observers, cannot be considered as sustained by these experiments. On the contrary, the action of the heart was in many cases the latest manifestation of life. Nor should we attach much more importance to the fact that the blood was tarry and coagulated badly in the dogs thus poisoned (M. Rabuteau), because this has been observed in all cases of sudden death from asphyxia. Cubic and prismatic needle-shaped crystals have also been found in the blood and white granulations, which were considered as chloride of silver, but which in reality are often found in normal blood after coagulation, and are the well-known crystals of hæmato-crystalline and of creatinin.

In seven experiments made on dogs and one cat, which presented all the symptoms of argyric intoxication after hypodermic injection of the hyposulphite of silver, the blood examined during the period of asphyxia, immediately after death, and the next day, showed neither crystals nor granulations of chloride of silver, but was normal; and only when it commenced to alter was there found, in one case only, the prismatic crystals of hæmato-crystalline. The blood of all the batrachians, saurians, fishes, birds, and the other mammifera examined under the above conditions has been found in every case perfectly normal, and presented no trace of granulations or crystals.

I do not deny, on the contrary I can only explain the special action of the silver on the nervous and muscular systems by admitting, that it circulates in the blood, mixed and combined with plasma, probably in the condition of an albuminate, thus being carried to the primitive elements of the tissues associated with the nutritive principles furnished them by the blood. Is the blood itself altered by that association, and has it lost any of its normal physiological properties? Nothing has shown it thus far, and the blood which carries in the organism a fatal dose of a compound of silver does not appear more altered than one which only contains a proportion of the toxic agent compatible with health and life and which produces only very slight or inappreciable effects. It seems that the blood plays the rôle of an agent of transport indifferent itself to the action of the toxic principle, at least in the methods of experimentation to which I have confined myself,—that is to say, when the salts of silver enter the blood by the way of absorption.

Conclusion.—Whatever may be the apparent variety of the phenomena which take place in the animals of different species, from the salts of silver introduced by *absorption* into the organism, these phenomena are always the direct consequence of the intoxication of the elements of the encephalo-rachidian nerve-centres, complicated in some cases by the intoxication of the muscular elements pertaining to animal life.

The blood which carries to the tissues the toxic substance, which it has received by the way of absorption, is not apparently altered either in its elementary composition or normal properties.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

SATURDAY, OCTOBER 18, 1873.

EDITORIAL.

DR. SHARPEY, of London, has recently had a narrow escape from death, caused by his taking inadvertently a solution of atropia for quinine. The symptoms developed themselves very curiously, as nothing was felt calculated to alarm Dr. Sharpey, who knew he had taken atropia, but thought the solution was a weak one, until about 1 P.M., some hours after the mistake, when he fell suddenly senseless to the floor, where he was found by a servant attracted by the heavy fall. Dr. Thane was summoned, and arrived at the house in a short time. He says, *inter alia*:

"I found the patient sitting on the floor, supported by two servants, making futile efforts to rise. He was unconscious, and speaking incoherently at intervals. The skin was hot and pungent, face flushed, veins of forehead turgid, and head burning. Pupils slightly dilated, conjunctiva not injected, breathing natural, pulse 110, irregular, generally full, but varying much at intervals; heart's action irregular, and apparently obstructed; teeth and lips dry, and covered with sordes.

"We immediately placed him on the bed, but had great difficulty in keeping him there, as he was extremely restless and wanted to get up. He had no paralysis, moving all his limbs freely and forcibly.

"He became more restless and delirious, talking constantly about his affairs apparently, and busy with his hands, pulling the bedclothes about. On asking him loudly if he had any pain in the head, he replied, 'No pain whatever.'

"It now became impossible to keep him in bed, and very difficult to prevent his walking about. He ex-

pressed a constant and frequent desire to pass water, but did not succeed in doing so. The bladder was found empty on percussing the abdomen."

For the further details of the case, as given by Dr. Sydney Ringer, we must refer our readers to the London *Lancet* of September 27, contenting ourselves with the statement that Dr. Sharpey was very delirious all night, but by 9 A.M. the next day had entirely recovered consciousness.

Speaking of his own sensations, Dr. Sharpey writes:

"I have no recollection of this fall, nor of what occurred for some time after, but I was speedily attended to by Dr. Thane of Montague Street and his son, and at a later hour also by yourself.

"The first thing I can recollect is, that I was struggling with people in the room, among whom, as I afterwards learnt, were Dr. Thane and yourself, also my nephew, Mr. George Goodall, whom I at once recognized when he told me who he was. I suppose I must have been very fractious in my delirium. I imagined I had to go off by a railway-train which started at ten in the morning, and that the hour was approaching, whilst I had nothing ready for the journey; and I believe that I wished to dress, and to pack my things, but was thwarted and prevented by the people about me. At length I was persuaded that it was too late to catch the train, and agreed to wait till the evening. I may here explain that I had come from Scotland by rail on the previous Thursday. I then became sensible that I was lifted into bed, and ordered on no account to rise, which I thought a most unreasonable restraint, especially as I was tormented with irritation in the bladder, and almost incessant desire to pass urine, which was in very small quantity. In this way I passed a very restless night, but slept fairly in the morning. Meanwhile my head began to clear; I remembered having taken atropia, and then was able to attend to my condition with some degree of intelligence. I had an intense feeling of dryness in my throat, which I knew to be an effect of the poison; this abated towards morning; then, although I could move my body and limbs, it was only by a great effort, and when I raised my arms they felt as if made of lead. This I ascribed to partial paralysis of the motor nerves, and I watched with some interest the return of power as the night advanced. As to my sensations, they were not blunted, but I misinterpreted them. Thus, I felt a wet cloth on my head, but supposed I had been out in the rain without my hat; and a dose of bromide of potassium given to me I recognized as a saline solution, but imagined it was mineral water from the Airthry spring, which I had tasted on the spot some ten days before."

AMHERST COLLEGE has given its LL.D. to Dr. Nathan Allen, famous for his researches in vital statistics.

RESPECTABLE physicians in this city have recently received through the mails a small pamphlet of sixteen pages devoted to the subject of medical electricity, and especially to its marvellous curative effects in diseases of all kinds as used by the utterer of the pamphlet and Madame his wife. Along with the usual clap-trap of free consultation, pictures of men with lumps ("fungus hæmatodes!") in the sternal region as large as their heads, and the same after three weeks' treatment with scarcely the trace of a scar, lists of references, certificates from persons who have been speedily cured of incurable disorders,—*en passant*, there is a suggestive resemblance between the literary style of the author and that of the writers of these letters,—along with these insignia of quackery is a proposal to practitioners of medicine offering ten per cent. of the fees obtained from victims sent to the author for electrical treatment. We have seen rampant quackery, we are accustomed to the barefacedness of charlatanism, but this offering of a sop to Cerberus seems to us the sublimest height of impudence ever scaled by genius! Who'll be the gudgeon to take the bait?

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPTEMBER 25, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. J. M. BARTON presented a pair of *fatty kidneys* from Mrs. C., æt. 49 years. She had been a healthy woman until she began to lose strength, about eight months ago. When the doctor first saw her, in the early part of September, both limbs were œdematous and greatly enlarged, which had been their condition for the previous four weeks; the right one was particularly large, and also the seat of an attack of erysipelas,—the immediate occasion of her requiring medical services. The urine was high-colored and scanty, and contained a large amount of albumen. On microscopic examination many free fat-globules and some hyaline casts were found. No fatty casts were discovered, though carefully sought. At first the patient improved, the erysipelas disappeared, the œdema diminished, the urine became increased in quantity and less high-colored; but on the 17th uræmic coma appeared, the case terminating fatally in forty-eight hours, during which scarcely any urine was secreted.

Autopsy.—Drs. S. D. Gross and Porter present. A few ounces of fluid were found in both the peritoneal and pleural cavities, particularly the left pleural. The kidneys were enlarged and quite white externally. On section a considerable quantity of fluid blood appeared at the most dependent portion. The capsule was readily separated; lungs and spleen healthy; liver cirrhotic; heart small, pale, and flabby, but with no evidence of valvular disease.

Dr. WILLIAM PEPPER presented a *heart showing*

marked hypertrophy with dilatation, and also disease of the aortic valves, two of which were apparently fused into one, owing to a separation along the entire line where one of each of their ends was inserted into the aortic wall. The leaflet thus formed was reverted, so that free regurgitation took place.

Dr. PEPPER also presented a *specimen of aneurism of the aorta dissecting into the walls of the right ventricle*, removed from a man who was admitted to the Philadelphia Hospital in the morning and died on the evening of the same day. The heart was also enormously enlarged, weighing thirty-five ounces. The pericardium was tightly adherent throughout. A tumor was found projecting itself into the right ventricle, forcing its way through the muscular structure of the heart, a part of the wall of the sac being covered by the lining membrane of the heart. On cutting into it, he found it to be an aneurism about four inches in diameter, partly filled with dark clotted blood and partly with decolorized laminæ of fibres. It communicated with the aorta just above the valves by a mouth an inch and a half in diameter. This aneurism of the aorta, arising behind one of the valves and enclosed in the pericardium, had attained such a size as to cause absorption of the muscular wall of the heart, or to force itself between the muscular trabeculae, and finally to project itself as a round mass into the cavity of the ventricle. Death had occurred from rupture of this aneurism into the pulmonary artery, immediately above one of its leaflets, by an opening one-half inch in diameter. The left side of the heart is moderately enlarged, the walls are thickened, and the cavity dilated. The aortic valves are healthy.

Dr. ALISON presented, for Dr. J. C. WILSON, a *pair of contracted kidneys*. The specimens were removed from the body of a gentleman aged 76 years, who had during many months exhibited signs of impaired health, but refused to call medical aid until a short time prior to his death. When first seen, July 8, 1873, he presented symptoms of advanced renal disease, complete loss of appetite, vomiting on taking food, occasional puffiness of face and eyelids, and œdema of hands and feet, most marked in the left side, but at no time very great. The urine averaged from two to three pints daily, was light-colored and limpid. Owing to the fact that the quantity sent for examination was always small, its specific gravity was not ascertained; and, for the same reason, it may be, no casts of any kind were discernible in the slight flocculent sediment that it deposited on standing. On testing it for albumen, coagula were formed which varied in amount from one-half to one-third part of the total bulk of urine examined. The liver-dulness was slightly decreased; the heart-sounds were distant and feeble; there was no murmur.

August 23, the patient had a severe and prolonged epileptiform convulsion, and from that date until his death, on September 15, he showed a varying degree of mental dulness, and had occasionally slight convulsive seizures. It is interesting to note that there was no lividity of the skin or lips, except during the convulsions, although he was evidently suffering from uræmia.

At the autopsy the heart was found to be enlarged (dilated hypertrophy) and fatty. Its muscular structure exhibited upon microscopic inspection granular and fatty deposit, obliterating in many places the transverse striæ. There were atheromatous deposits at the bases of the aortic valves and in the aortic arch.

The liver was smaller than usual, but normal in appearance.

The kidneys were small, the contraction being most marked in their long diameter; the surface coarsely granular and studded with minute cysts, the capsule everywhere so tightly adherent that it was impossible to separate it from the kidney-substance, the cortex atrophied, the pelvis and calyces filled with fatty tissue.

The tissues of the body were everywhere loaded with fat. This gentleman was a good liver.

Dr. W. G. PORTER exhibited a *necrosed astragalus* removed from O. H., aged 22, laborer, a native of Wales, temperate in habits. He was admitted to the Presbyterian Hospital July 21, 1873. He was unable to speak a word of English, but the men who brought him stated that his foot had been injured by the caving in of a bank of earth. After careful examination by Drs. Allis and Hodge, a diagnosis of luxation of the astragalus inwards was arrived at. An unsuccessful attempt at reduction was made: this was within half an hour of the reception of the injury. The man was kept quiet in bed, and evaporating lotions were applied, until all inflammatory symptoms had subsided.

July 31st, he came under Dr. Porter's care. All pain and inflammation had disappeared. The dislocated astragalus could be distinctly felt beneath the skin, close behind the inner malleolus. He was kept in bed till the 17th of August, when he was allowed to rise and encouraged slowly and carefully to use the foot, first with crutches and then with a cane. On the 28th of August he was suddenly seized with a chill, followed by violent constitutional irritation. Sloughing of the integuments over the bone rapidly followed, and in a few days a considerable portion of the bone was exposed. The pulse was considerably excited, and the temperature varied from 102° to 104° for several days. The amount of suppuration was not very great, and on the 25th of September Dr. Porter removed the loose bone, by forceps alone, and without enlarging the wound; a portion of the bone, being soft, was crushed by the forceps during the removal, but the fragments were removed without difficulty.

Dr. J. H. CATHCART presented a pair of *cystic kidneys* from Mrs. G., æt. 45 years, married. She has been suffering from trouble with the lungs for the last eleven years; had typhoid fever eight years ago. Complained of pain in the left side, and at times in the back, resembling somewhat uterine pains. They yielded to small doses of anodyne, and the doctor thought they might be caused by flatulence. Only once was his attention called particularly to the urinary organs; and that was from the expulsion of a stone from the bladder. She then had not suffered any exacerbation of pain in the side or back. He asked her to save some of the urine, but she failed to do so, after repeated requests. It was not, therefore, examined.

The cysts in the kidneys were lined with inorganic matter of undetermined composition, but there was no calculus in the kidney or its pelvis.

Dr. JAMES TYSON thought the question might be raised as to whether these cysts were not the result of degeneration and breaking down of a cheesy deposit, or matter similar to that contained in the lungs; but he thought the view which ascribed them to an impacted calculus, even though none was found in the kidney post mortem, was the most reasonable one.

The PRESIDENT inquired the size of the calculus which had been passed.

Dr. J. S. PARRY said he first saw the patient in consultation with Dr. Cathcart about a year ago. She was then suffering with phthisis. He did not see the calculus, but, after a good deal of trouble in investigation, he concluded it must be as large as a filbert. Its expulsion was followed by a gush of urine, and great relief to the patient's symptoms.

The specimen was referred to the Committee on Morbid Growths, who reported as follows:

"Your committee have examined the kidney presented at the last meeting by Dr. Cathcart. The infiltrated zones of the ulcerated irregular patches in the cortical substance were carefully searched for any evidence of tubercle. Nothing having been found be-

yond the indurative thickening of all the connective tissue in the immediate vicinity of the ulcerations, your committee beg leave to report that they do not regard this as a case of 'phthisis renalis,' but as one of local sclerosis and destruction, such as would naturally ensue from the presence of a foreign body."

GLEANINGS FROM OUR EXCHANGES.

ASPIRATION OF URINE (*The Clinic*, August 30, 1873).

—Dr. James T. Whittaker reports the case of a young man, æt. 18, who, in the midst of a nightmare, leaped out of his window and fell forty feet upon a brick pavement. He was seen the next morning, when he was in apparent collapse, cold and pulseless, the abdomen distended to its utmost, and the face anxious. There were a Barton's fracture of the left wrist, a compound comminuted fracture of the same elbow, fracture of the horizontal ramus of the pubes, and terrible contusion of the left hip. A catheter was introduced with the greatest difficulty to the neck of the bladder, when four ounces of dark, grumous blood escaped, and afterwards a small quantity of urine. All subsequent attempts at catheterization proved futile. The membranous portion of the urethra could not be passed at any time, and it was believed that it was torn across at or near the neck of the bladder, and that the vesical orifice was closed by coagula. The catheter could be felt by the finger in the rectum to leave the urethra and glide along between the rectum and the bladder.

As the bladder was greatly distended, it was decided to use Dieulafoy's aspirator; and, accordingly, the urine was drawn off through a puncture made in the median line just above the pubes, the method being now so well known as to render description needless. The operation was repeated every morning for eight days, at which time a few drops of urine began to pass *per urethram*, and in two days more he could pass his urine as well as ever, and all abdominal symptoms subsided. He has now every prospect of a complete recovery. No precautions whatever were taken in making the punctures, and when the bladder was emptied the trocar was withdrawn in the same manner as the hypodermic syringe, without even making pressure upon the orifice.

Dr. Whittaker believes that capillary hypogastric puncture is a perfectly harmless operation; that in all cases it should be substituted for ordinary hypogastric puncture; that in a great number of cases it may, when only once practised, allow the surgeon to penetrate afterwards into the bladder through the natural passages; that in certain cases where catheterism is impossible it may be performed three or four times a day without any injurious effect, and thus permit the surgeon to gain time and restore the natural passages; and that, at the very least, it constitutes a palliative means of the highest importance. Quoting Dr. Little, the following rules are suggested for the operation:

"1. The patient should lie on his back, and, if the bladder is not much distended, the operation will be facilitated by slightly elevating the patient's hips by means of a pillow placed beneath them.

"2. The puncture should be made on or near the median line, from one inch to one inch and a half above the pubes, and should be made each time in a different place. In the case described, the punctures were about a line apart and extended over an area about half an inch in diameter. Mr. Watelet recommends the No. 2 capillary trocar; but in cases where cystitis exists and the urine is loaded with pus, mucus, or the phosphates, one of the larger trocars may be used with safety.

"3. The bladder may, when necessary, be washed out by filling the cylinder with water from the basin, and reversing the action of the instrument, without withdrawing the trocar from the bladder."

MEAT-TEA.—Bogoslowsky (*Arch. f. Anat. u. Physiol.*, 1872, 347, 428, and *Centralblatt*, 1873, p. 279) has re-examined the theories of Kemmerich in regard to the action of meat-tea, which was supposed by him to depend wholly on the potash salts contained therein. Bogoslowsky says that Kemmerich used too large doses, and that the fact that a rabbit can be killed not only by a large amount of beef-tea, but by the salts extracted from a similar amount, proves nothing except that both are (in enormous doses) poisonous.

With small doses the difference is a marked one. While, for example, a rabbit was killed by the injection of extract of 700 grammes (1 pound 10½ ounces) of meat reduced to 30 cubic centimetres (about 1 ounce), the ashes of the same quantity dissolved in 30 cubic centimetres of water produced in another rabbit only a transient acceleration of the pulse, and the animal completely recovered. Nine days after, it died in an hour and a half after the ingestion of the corresponding quantity of meat-tea.

It was shown that injections of warm water cause an increased rapidity of the pulse, but of meat-tea, a much greater and more lasting acceleration. The salts hardly differ from warm water, or, in larger doses, the acceleration may last somewhat longer.

The author was able to produce these phenomena to a slight degree in his own person, but in another individual did not succeed. After larger doses (10, 20, 30 grammes), in the latter case, the pulse fell, while the thermometer was unchanged. After 40 grammes gastric symptoms appeared, and the pulse rose. He concludes, as a practical result, that extract of meat is not so innocent a dietetic substance as is generally supposed, but always calls for care in its administration. (If Liebig's or any similar extract is here referred to, it would seem that the danger is not great unless the quantity used considerably exceeds that mentioned in the directions accompanying the packages.)

In endeavoring to determine to what ingredient meat-tea owed the excess of its action over that obtained from the salts, Bogoslowsky found that creatinin, which exists in extract of beef in considerable quantities, when injected either into the jugular vein, under the skin, or into the stomach, produced a slight acceleration of the heart's beat, but he could not get any fatal effect.

From all which it appears that the stimulant action of ordinary doses of beef-tea is due partly to the warm water, the salts, and the creatinin. It would seem, however, from the observations last quoted, that the presence of creatinin is not sufficient to account for the difference between the action in beef-tea and the salts obtained therefrom. It is only in exceedingly large doses that the salts alone are sufficient to account for a fatal effect by their depressing action upon the heart.

Leube (*Berliner Klin. Wochenschrift*, 1873, Nos. 17 and 19, and *Centralblatt*, 1873, p. 491) has made use of the following method of preparing a solution of meat, to replace the complicated and costly process of Meissner with natural pepsin, which is, besides, objectionable on account of the disagreeable taste and smell of the product. 1000 grammes of lean beef is placed in a porcelain pot, with 1000 cubic centimetres of water and 20 cubic centimetres of pure hydrochloric acid. The mixture is heated in a Papin's digester for ten or fifteen hours, and occasionally stirred. The mass is then rubbed down in a mortar to the consistence of an emulsion, and boiled fifteen or twenty hours more without the cover of the digester being lifted. It is then neutralized with carbonate of soda, evaporated to the

consistence of a pap, divided into four portions, and dispensed in pots.

The muscular fibres are broken up to a fine detritus, and the greater part of the albuminoid constituents is dissolved. The preparation is well borne and willingly taken, but it is better to use some other easily digestible food therewith,—in order not to disgust by too constant use. The taste may be improved by the addition of Liebig's extract.

The solutio carnis has been used in acute gastric ulcer and in chronic dyspepsia. It is supposed to give rest to the stomach by sparing it the labor of digestion, the albuminoids being already converted into peptones. —*Boston Medical and Surgical Journal*.

ESMARCH ON THE PREVENTION OF HEMORRHAGE DURING OPERATIONS.—In the *Berliner Klin. Wochenschrift*, No. 32, 1873, is reported Professor Esmarch's method of preventing hemorrhage during operations. At the second congress of German surgeons, he made an important communication, "Ueber Blutersparung bei Operationen an den Extremitäten." In a few words, the plan consists in emptying as much as possible the blood from the extremity to be operated on before commencing the operation, and then, during the operation, preventing, by powerful compression, any blood from gaining access to the limb.

For instance, when a sequestrum is to be removed from the tibia, an elastic or other bandage is to be applied from the tip of the toes to the middle of the thigh whilst the patient is being chloroformed. This must be applied tightly enough to drive the greater part of the blood in the capillaries and veins towards the heart. Above the bandage an india-rubber tube, about as thick as the thumb, is then stretched tightly around the thigh, so as completely to arrest the circulation. If the subject be muscular, a pad is placed over the course of the chief artery.

The bandage may now be removed, and the operation commenced. The skin of the limb is quite pale, and no pulse to be felt anywhere in it. With the first incisions, a little dark blood may come away from the deep veins, but this speedily ceases, and the operation may be completed *wie an der Leiche*; no more blood flows than from a corpse, and the operator is not embarrassed by the blood welling up in the wound, nor by the assistant's sponges. Those accustomed to the often profuse bleeding during operations for necrosis will hail this innovation with delight. The hemorrhage is sometimes dangerously profuse, while it is difficult to control, and renders the operation more difficult. Dr. Esmarch observes that the sensation he experienced when he first employed this method was one of lively regret that so simple and efficient an expedient had not been before resorted to.

The reporter has tried this method himself in a case of necrosis of the tibia; and he is able to state that during the entire operation, lasting nearly a quarter of an hour, not one single drop of blood flowed, and the wound remained perfectly dry throughout. Every portion of the wound remained unobscured by either the oozing of blood or the sponges of the assistants. The facilities thus afforded to the operator were very great, whilst the patient, a very delicate weak child, was surely better for being saved all loss of blood. No unpleasant effects attended the use of the elastic apparatus. His colleague, Mr. Arnot, has since tried it in an excision of the knee-joint. Not a drop of blood flowed during the half-hour the operation lasted. This plan will no doubt be extensively resorted to.—*William MacCormac, in London Medical Record*.

MENSTRUAL JAUNDICE.—The close relation existing between disturbances of the female sexual organs and

affections of the liver is well known, to which is perhaps due the relative frequency of hepatic disease in females. Senator has recently contributed an article in which he draws attention to the hitherto apparently unobserved coexistence of menstrual disturbances and jaundice. Four cases are recorded, in all of which, up to five repetitions, before or during the menstrual period, with slight or no loss of blood, jaundice appeared, continuing several days, and accompanied by corresponding constitutional disturbance and gastric derangement. With the appearance of a more copious flow the symptoms disappeared, leaving the patient well up to the next menstrual period. It was evident that the cause was biliary obstruction, from the simultaneous enlargement of the liver, the clay-colored stools, and the presence of biliary salts in the urine, which were detected in one case. One of the patients complained of hemorrhoids for the first time during this period. Another of the cases was interesting in having been affected three times during the first months of a pregnancy, one and a half year before the occurrence of the attacks of menstrual jaundice, with jaundice benign in character, which is remarkable, as jaundice is usually malignant when occurring in connection with pregnancy.

Senator accounts for this condition by a hyperæmia of the liver, which can easily cause swelling of the mucous membrane of the biliary passages, and their consequent occlusion. It is well known that obstructed menstruation is frequently accompanied by hyperæmia of the liver, as also of other organs, as the thyroid body, and that vicarious menstruation from the stomach, lungs, nose, etc., takes place.

Though the disturbances occasioned by menstrual jaundice may be slight and transitory, remedial interference is nevertheless recommended, to prevent the possibility of the accession of some severer form of hepatic disease. In the above cases the use of the warm bath, with the internal use of Carlsbad salts, with moderate diet, was found beneficial.—*New York Medical Journal*.—*Centralblatt*, 1873, No. 14.

TREATMENT OF THORACIC ANEURISM BY ELECTRO-PUNCTURE.—The patient with thoracic aneurism, whom Mr. Beck has been treating by means of electro-puncture, died on Tuesday night. He was suffering from a large and rapidly growing aneurism of the descending aorta, which not only caused bulging of the lower ribs on the left side, but had eroded several of them, and gave rise to a pulsating tumor just below the angle of the scapula. Mr. Beck first operated on the 2d instant; he inserted the wires into the most prominent part of this tumor, and passed the current between them for about an hour and a quarter. The effect, as we stated in the *Journal* of the 6th instant, was very encouraging; the tumor became decidedly firmer, the impulse less heaving, and the pain was greatly diminished; there was no irritation about the seat of puncture. This improvement lasted five or six days, when the impulse became stronger, and the tumor began again to enlarge. On the 10th Mr. Beck repeated the operation; but this time the improvement was but slight, and of a still more fugitive character. A few days afterwards, it was found that some inflammation had been set up round one of the punctures; and, on pressure, a small quantity of pus escaped. The aneurism, though it never became absolutely diffused, now spread rapidly under the skin of the back, and it was found that the dullness was extending upwards over the left side of the chest; that the heart was being pushed more and more to the right, and the lung becoming compressed. The aneurism, as the necropsy showed, had burst into the left pleura. The patient gradually sank, and died of exhaustion. Before death, the skin round the inflamed

puncture had become quite dark and gangrenous. The lesson from this case is, that treatment by electricity must be commenced at an early period of the disease, in order to give any prospect of success. That it does induce extensive coagulation in the sac, seems evident; and it is very desirable that any method which gives reasonable hopes of curing what has hitherto been a necessarily fatal disease should be thoroughly tried before being condemned.—*British Medical Journal*.

THE USE OF ERGOT.—Dr. T. K. Spendee writes (*British Medical Journal*) as follows: "I have given ergot in some cases of neuralgia, according to the advice of Dr. Woakes, of Luton; but, though I have had particularly good results, I have not been able to remove pain entirely by the use of ergot alone. I can endorse all the favorable views of ergot in the treatment of hæmoptysis, as related by Dr. Dobell and Dr. Anstie. I have used the medicine for this purpose during several years past, having been originally led to do so by a consideration of its therapeutic analogies. It does not yet seem to be clearly defined whether there is any stage of phthisis, even the most advanced, which is absolutely beyond the control of ergot, when spitting of blood occurs. Of the exceeding value of the medicine in these cases (though it now and then unaccountably fails), there can be no doubt whatever; and, as the facts are very little known, attention cannot be too often called to them. The action of ergot on the uterus is a proverb: why should it not affect in a similar way a neighboring organ,—the bladder? I have found that that quasi-paralytic condition of the bladder, which may come on in middle-aged persons from over-fatigue or from simple want of power in the coats of the organ, is greatly relieved by the continuous use of ergot, and may be altogether removed. The so-called hysterical paralysis of the bladder in young women is admirably treated with the same medicine (though I cannot deny the occasional necessity for the use of the catheter). Whether this want of power be simply motor weakness, or secondary to some variety of abdominal neuralgia, there is no more splendid combination of medicines than ergot and strychnia (half a drachm of the fluid extract of ergot and five or six minims of the *liquor strychniæ*, Ph. B., in chloroform-water, three times a day); and these doses should be continued perseveringly for several weeks, as a very rapid benefit cannot be expected.

TRAUMATIC DESTRUCTION OF ONE CEREBRAL HEMISPHERE WITHOUT FUNCTIONAL DISTURBANCE.—The eminent Italian surgeon Porta brought before the Institute of Lombardy, on the 19th of December, 1872, the case of a man who, in consequence of a severe injury, lost the whole of the right hemisphere of the brain. The unconsciousness lasted a few hours, but when the patient recovered his senses he recollected being picked up and taken upon a cart to the hospital. He stayed two months and a half in the institution, the skull exfoliated, and the wound became fungous, when he claimed his discharge, though affected with paralysis on the left side, which had occurred immediately after the infliction of the injury. He subsequently applied at the clinical wards of Pavia, where Dr. Porta had an opportunity of studying the case. Eighteen months had elapsed since the accident, and twelve months since the closure of the wound. The author minutely describes the integrity of the intellectual functions, the amount of paralysis in the upper and lower limbs, and concludes by dwelling on the three following points: 1. That the encephalon is a double organ, composed of two equal parts, and that, one being destroyed, the other survives without functional disturbance. 2. That in the different spheres of the cerebral, medullary, and nervous system, special and diverse functions are perfectly isolated and localized, the disturbance of the

functions following localized injuries. 3. That, in the present case, electricity diminished the paralysis of the arm, and that the improvement would have been more marked had the treatment been sufficiently prolonged.

The case is confirmatory of the well-known experiments on the lower animals, from whom a whole hemisphere was removed.—*London Lancet*, Sept. 6, 1873.

THE DELIVERY OF THE PLACENTA BY SUPRA-PUBIC PRESSURE.—Judging from our own experience, and from the number of laudatory papers on this subject, Credé's method of delivering the placenta, or some slight modification of it, bids fair to take the place of every other. The plan which we adopt is as follows. At the maximum of the first uterine contraction after birth of the child, the fundus of the womb is grasped through the abdominal wall, between the thumb in front and the fingers behind. It is then to be both forcibly squeezed and at the same time pressed downward and backward. By means of this uterine expression the placenta and membranes are usually at once detached and extruded. Sometimes, indeed, they will suddenly pop out of the vulva, just as the stone escapes when a cherry is compressed between the finger and thumb. Occasionally it will require two or more pains to effect this; but the sooner this plan is resorted to after the birth of the child, the more easy in execution will it be. Those who, like ourselves, practise this method, contend that it offers many advantages over any other. The risk of communicating any puerperal disease is lessened. The expulsion of the placenta and membranes by a *vis a tergo* is more likely to be complete than by traction on the cord, which cannot be broken, as no traction is made on it. Adherent placenta is less frequently met with. The introduction of the hand into the womb is avoided, and so also, as a consequence, is the ingress of air. Finally, the tonic and energetic contraction of the womb, following this manœuvre, prevents the occurrence of hemorrhage or of unruly after-pains.—*Goodell, in Transactions Med. Soc. Penn.*, June, 1873.

POISONING BY WILD PARSNIP [*Sium latifolium* OF GRAY] (by C. B. White, M.D., U.S.A.).—On April 24, 1873, I was called, after dark, to assist E. C., a native of Belgium, aged 49 years, nearly twenty-one years a resident of California, who was suffering from the effects of eating less than one ounce (estimated) of the fresh root of the wild parsnip.

On my arrival, I found that he had received partial relief from vomiting and purging, apparently induced by the root itself, but I found him much excited and very prostrate in strength; pulse 44, skin cold and clammy, pupils somewhat dilated, respiration slow. He complained of great dizziness, lack of mental power, and loss of voluntary motion, headache, sense of fear of death, with a decided burning feeling along the alimentary tract (œsophagus especially), and sense of swelling and flatulence about the bowels. I examined the excreta and became satisfied that most of the root had been ejected, and at once gave him two ounces of whisky, mixed up with a raw egg. After this had revived him, I administered morphine sulphas, gr. one-fourth, and left a compound ipecac powder for later use.

Before I left him he was feeling much better in every way, the skin was warmer, the pulse 50, the respiration and the appearance of the eyes nearly normal.

PRECOCIOUS MENSTRUATION.—Dr. R. K. Clark details (*Western Lancet*, Sept. 5) the case of a girl who, soon after completing her fifth year, complained to her mother of pelvic pain and the usual symptoms of approaching menstruation. She soon had a sanguineous show, which continued for three days and then ceased,

but has appeared regularly once in twenty-eight days ever since. She is not precocious in any other respect, not large of her age; but the usual change in form suited to a young lady fifteen or sixteen years of age has taken place, so that she looks like a little woman. An aunt of this child is said to have menstruated at six years of age and continued till she was thirty-eight.

MISCELLANY.

CULTURE OF THE OLIVE IN AUSTRALIA.—The plant is correctly stated as being easily propagated, and from its hardy, drought-resisting nature, the ease with which it can be grown, and the small amount of skill and labor required in its cultivation and in the manufacture of its products, it seems specially adapted to the circumstances of the colony as well as to its soil and climate. As a shelter-plant to break the strong winds, and for planting around dwellings in the country and giving to them that air of snugness so often painfully lacking in the appearance of bush-houses, few plants equal and none excel the olive. The habit of growth is sturdy and compact, the form and color pleasing to the eye, and, in addition to these desirable qualities, the fruit is profitable, so that in this ancient friend of man the useful and ornamental are combined. Taking these facts into consideration, there seems no reason why the roadsides of civilized Australia should not be lined with olive-trees, but, on the contrary, there is every reason why they should, as in the fulness of time no doubt they will be.

With the increase of machinery the demand for oil increases, and in fact the market for it is practically unlimited. In South Australia, from the fruit of trees twenty years old an annual yield of ten gallons of oil per tree has been obtained, which, at 6s. per gallon, gives £3 per tree as the value of the produce. True, the olive cannot be regarded as a source of immediate profit. It requires time before it will bear fruit. Some planted eleven years ago in West Australia are now coming into bearing. On the other hand, the olive-tree is of a very enduring character, and with age increases in value. These characteristics have given rise to the Italian adage, "He who wants to leave a lasting inheritance to his children should plant olives."—*John R. Jackson, A.L.S., in Food Journal*.

THE salt-mines discovered in the Teche country, Louisiana, during the late war, are now being worked, while the surface is covered with growing sugar-cane. The bed, estimated to contain ninety million tons of pure solid rock-salt, is located on an island of 300,000 acres, rising 185 feet above a salt marsh. Access is obtained to this island by a steamboat-line running between Brashear City and New Iberia. The soil is composed of sand, loam, gravel, and clay, and the surface is partially covered with magnolia, live-oak, cypress, maple, locust, gum, walnut, and fruit-bearing trees. The vegetation resembles that of a rich prairie, and the scenery is varied and beautiful. Access to the interior of the salt-mines is obtained by an elevator, running up and

down a forty-foot shaft cut through the solid material. The width of the vein is 120 feet, and the visitor is surrounded on all sides by rock-salt as dry as powder. The absence of moisture is one of the most striking peculiarities, and the iron and steel implements used are quite bright. Two large chambers have been cut out of the vein.—*North American*.

A USEFUL SOAP.—The following is commended, by those who have tried it, for scrubbing and cleansing painted floors, washing dishes, and other household purposes: Take two pounds of white olive soap and shave it in thin slices; add two ounces of borax and two quarts of cold water; stir all together in a stone or earthen jar, and let it set upon the back of the stove until the mass is dissolved. A very little heat is required, as the liquid need not simmer. When thoroughly mixed and cooled, it becomes of the consistence of a thick jelly, and a piece the size of a cubic inch will make a lather for a gallon of water.—*Boston Journal of Chemistry*.

RYE COFFEE IN EUROPE.—A Strasburger named Beckmann Oloffen has prepared a substitute for coffee by taking pulverized and roasted rye malt, mixing with it one-twentieth its weight of barley malt and some caramel, and exposing it to the vapor from roasting genuine coffee. In this manner part of the aroma always lost in roasting coffee is made use of to flavor the rye coffee. If we accept the conclusions of Aubert, that no caffeine is lost in roasting, the rye coffee has none of the poisonous properties of this alkaloid, and is preferable to the genuine. The discovery is said to have been already patented in England.—*Druggists' Circular*.

TO KEEP GUM ARABIC FROM MOULDING.—Solutions of gum arabic soon mould and sour, and finally lose their adhesive property. It is said that sulphate of quinine will prevent this, while it imparts no bad odor of its own. The addition of a solution of a few crystals of this salt to gum arabic will prevent the formation of mould quite as effectually as carbolic acid, and by analogy it is safe to suppose that the same salt could be used in writing-ink, mucilage, and possibly glue.—*Druggists' Circular*.

MODE OF ADMINISTERING CREASOTE.—As creasote is now frequently employed in the treatment of typhoid fever, and is exceedingly distasteful to some patients, it may be worth while to mention here a formula which in a great measure covers its flavor, and is easily prepared: Creasote, 3 drops; essence of lemon, 2 drops; orange-flower water, 1 ounce; spring-water, 3 ounces. A spoonful to be taken at frequent intervals throughout the day.—*Canada Medical Journal*.—*Virginia Clinical Record*.

THE great fire at Chicago in the autumn of 1871 has produced a large number of lunatics, no fewer than 250 sufferers from it having been adjudged insane by the courts of Illinois.]

THE consumption of horse-flesh is rapidly increasing in France. During the first half of the year 1867, 893 horses or mules were slain for consumption, and afforded 320,000 pounds of meat; during the corresponding period of the present year, 5186 animals have been slaughtered, affording about 1,800,000 pounds of meat for public consumption. This is an enormous increase, and the utilization of horses unfit for work, but thoroughly healthy, and not worth more than about £4, will, it is reckoned, increase the public wealth by 400,000,000 of francs.—*London Lancet*.

FOR CHAFING OF INFANTS.—Take of powdered starch two parts, white oxide of zinc one part. Make a fine, well-mixed powder. Dust the abraded places with the powder, after proper cleansing.

THERE are several members of the profession in California who own vast tracts of land. Dr. Glenn, of Colusa County, possesses a ranch containing nearly 45,000 acres. It has a frontage of eighteen miles on the Sacramento River, and is enclosed and divided by one hundred and forty miles of fencing.

THE Bengal government (so telegraphs the *Times* correspondent) has ordered the extension of the medical vernacular colleges in Calcutta, Dacca, and Patna.

ON the 8th ult. Professor Hughes Bennett, of Edinburgh, was elected corresponding member of the National Academy of Medicine of France.

PROFESSOR CZERMAK, the celebrated physiologist, whose work on the laryngoscope was translated by the Sydenham Society, died on Monday, September 15, at Leipsic.

M. CLAUDE COLLAS finds in the application of sinapised paper a cure for the bites of gnats.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 7, 1873, TO OCTOBER 13, 1873, INCLUSIVE.

McKEE, J. C., SURGEON.—Relieved from duty in Department of the East, and to report in person to the Commanding General, Department of California, for assignment. S. O. 197, A. G. O., October 6, 1873.

ALDEN, C. H., SURGEON.—Relieved from duty in the Department of the Lakes, and to report in person to the Commanding Officer, Department of the Columbia, for assignment. S. O. 197, c. s., A. G. O.

WEBSTER, WARREN, SURGEON.—Relieved from duty in the Department of the East, and to report in person to the Commanding General, Department of California, for assignment to duty. S. O. 197, c. s., A. G. O.

McCLELLAN, ELY, ASSISTANT-SURGEON.—Assigned to duty at Headquarters Department of the South. S. O. 174, Department of the South, October 8, 1873.

HUBBARD, VAN BUREN, ASSISTANT-SURGEON.—Relieved from further duty at these Headquarters, and to join his station at Mississippi City, Mississippi. S. O. 158, Department of the Gulf, October 4, 1873.

BREWER, JOHN W., ASSISTANT-SURGEON.—Granted leave of absence for thirty days. S. O. 195, Department of the East, October 7, 1873.

DE WITT, CALVIN, ASSISTANT-SURGEON.—Relieved from duty in Department of California, to proceed to Harrisburg, Pennsylvania, and report by letter, upon arrival, to the Surgeon-General. S. O. 197, c. s., A. G. O.

GIRARD, A. C., ASSISTANT-SURGEON.—Assigned to duty at McPherson Barracks, Atlanta, Georgia. S. O. 174, c. s., A. G. O.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF RUPTURE OF THE AORTIC VALVES.

BY WILLIAM PEPPER, M.D.,

Lecturer on Clinical Medicine at the University of Pennsylvania.

GENTLEMEN:—I avail myself of the opportunity afforded me by the post-mortem examination of a case which has been under my care for the past four or five years, to speak to you of a very rare accident,—the rupture or separation of one of the valves of the aorta from a mechanical cause. These valves, more than any other part of the circulatory apparatus, are exposed to violence and overstrain. Thus, in all classes of laborers whose work involves a great amount of muscular exertion with the arms, a disproportionately large number of cases of aortic disease will be found. And the mode in which this result is brought about is readily explained. In persons so employed we find the heart, stimulated by the active exertions, contracting frequently and with great force; the aorta is of course correspondingly distended, and the pressure exerted to force forward the blood is extremely great. Under these circumstances it is evident that if anything occur to prevent the free onward movement of the blood through the vessels, the arterial tension must be greatly increased, and the recoil upon the valves of the aorta which close to prevent reflux into the left ventricle proportionately powerful. Now, the peculiarity of violent muscular exertions with the arms is that they tend to produce precisely such obstruction. Immediately before the effort, whether at striking or lifting heavy weights, a deep inspiration is taken, which aids in filling the cavities of the heart to their utmost, and then, in order to afford fixed points for the contraction of the muscles of the arms and shoulders and back, the chest is held rigidly fixed. The violent contractions of the muscles of the neck which follow compress the carotid arteries, while those of the muscles connected with the arms impede the free flow of blood through the subclavians and their branches. Thus, while the tension within the chest is greatly increased, and the heart is stimulated to violent contraction, there is also an enormous elevation of arterial tension. The strain which results must expend itself *directly* upon the walls of the left ventricle, which must over-exert themselves to press forward the blood; and *indirectly* upon the aortic valves, which are compelled to bear the shock of a recoil of the blood-stream violent in proportion. When such over-strain of these tissues is repeated hundreds of times daily, it will cause stretching of the parts, and later, when this has gone to a certain extent, a process of inflammation of a low grade will be established, which leads to thickening and softening, and subsequently to

contraction and stiffening, of the leaflets of the valve. You will not be surprised, therefore, to learn that such disease of the aortic valves is far most frequently found in men, and especially in those whose occupations compel them to make just such exertions as are above described. I have said that the gradual production of disease of the aortic valves under such influences is easily understood; but I wish further to direct your attention to the question whether it is possible that, in a person having no disease whatever of the heart or aorta, a sudden and most extreme effort with the muscles of the trunk and arms should cause such abrupt and violent stretching of the aortic valves as to rupture one of them, or tear it loose from its points of insertion.

It is by no means rare to find, on examining aortic valves which have been the seat of advanced disease, a laceration of one of the leaflets extending from the free border to a varying depth in the valve. The edges of the laceration are irregular, and the entire valve is thickened, and often calcareous and brittle. In such cases there has been a history of long-standing aortic disease with increasing amount of regurgitation, and of course the solution of continuity of one of the leaflets must have greatly favored this. I have found, more frequently than the above condition of laceration, a partial condition of separation of two leaflets from elongation of their common line of attachment to the aortic wall. This extremity of the leaflets is therefore no longer inserted on the normal level, and in consequence their free border must usually be more or less reverted when subjected to the pressure of the column of blood in the aorta, so that in this case also considerable regurgitation takes place. It will be found that valves which have been thus partially separated invariably present evidences of disease, and are thickened and usually shortened. The difficulty in such cases lies in determining what the condition of the valve may have been at the time the laceration or separation occurred.

In most cases there is no history of any sudden violent exertion followed immediately by symptoms of frightful disturbance of the heart's action, such as would ensue upon such an accident, but rather of gradually increasing cardiac disease, with occasional acute aggravations from ordinary causes; and the evidences of long-standing disease are so marked as to render it clear that the lesion of the valve has been the result of diseased action.

In some rare instances, however, the development of the symptoms of insufficiency of the aortic valves is so sudden, and comes on in the midst of apparent health, or after such slight evidences of cardiac disease, as to render it more difficult to decide as to the previous state of these valves. I know of no case upon record where such an accident has been suspected, and where death has occurred soon afterwards and it has been proved that a laceration of a previously healthy valve has really taken place. It has always happened that life has been prolonged for some time; and it then becomes difficult to determine with certainty whether the evidences of

disease of the valve have been entirely the result of the injury to its tissues, or whether there was not some previous morbid state which so weakened the valves or their attachments as to indirectly cause their rupture or separation. Although I cannot deny the abstract possibility of the laceration of a healthy valve, I am inclined to believe that the other will uniformly be found the real state of the case, as it undoubtedly was in the following remarkable case of almost complete separation of two aortic leaflets from the line of their common attachment to the wall of the aorta.

Case.—D. D., aged 35 years, a bar-keeper, first came under observation in the summer of 1868. He had enjoyed general good health until within a few years, when he suffered from several attacks of sub-acute rheumatism. For about eighteen months previous he had also felt some oppression and palpitation of the heart on exertion or after excitement. His habits were very intemperate and dissipated; but there was no evidence of his ever having had syphilis.

In April, 1868, while struggling to turn a windlass to raise a very great weight, he felt a sudden severe pain and sense of failing or *giving way* at the præcordia. He staggered and had to be helped to a seat. Those who helped him asserted that a curious whirring or fluttering sound became suddenly audible even to the distance of a foot from the chest, and at the same time violent tumultuous action of the heart (which had never before been noticed) became readily visible. He was obliged to throw open all his upper clothing, and beat himself upon the chest and clutch at his throat, in the extremity of his distress. Orthopnoea continued, and he passed the entire night sitting by an open window. The following day he began to spit blood quite freely. The pulse was estimated by the physician who first saw him to be 212 in the minute. No systematic treatment was adopted, save moderate stimulation and counter-irritation over the præcordia.

When first seen by me, fifteen days after the accident, his condition was as follows: Surface very pale; extremities cold and damp, and some œdema of the feet; mind dull, with occasional slight wandering; respirations (sitting) 35 in the minute, and labored; frequent cough, with expectoration of pure unœrated blood in large mouthfuls. Over both lungs, especially posteriorly, the respiratory murmur was accompanied by a fine crepitant râle, heard only at the end of inspiration. No fulness or pulsation of the jugulars; flapping, jerking, but feeble pulsation of the carotids at the base of the neck, and a faint murmur heard along the course of these vessels; radial pulse feeble, very small, 186 in the minute. The impulse of the heart was feeble, without any fremitus; the apex-beat was extended, and lay to the left of the vertical line of the nipple, and too low down; the area of cardiac dullness was somewhat increased; the heart-sounds were confused and tumultuous; at the apex no positive murmur could be detected, and there was no murmur transmitted towards the left axilla or heard at the angle of the left scapula. No murmur was audible at the xiphoid cartilage. At the third interspace, close to the left edge of the sternum, a distinct, short murmur was heard, which could not be timed, owing to the rapidity of the heart's action; it was transmitted up along the left edge of the sternum to the second interspace. At the aortic cartilage, a confused, tumultuous sound was heard which defied analysis.

He was ordered turpentine stupes to the chest; beef-tea and milk-punch. Tincture of digitalis was given also, in doses of gtt. x every third hour. On the fourth day the dose was increased to gtt. xx; and the next day, finding no relief was produced, another specimen of

digitalis was obtained and given in doses of gtt. x, q. t. h. After thirty-six hours' use of the latter, hæmoptysis ceased entirely; respirations fell to 24, and grew more easy and full; œdema diminished, though there was still some puffiness of the feet and face; pulse much fuller and stronger, 92 in the minute, distinctly jerking; heart's action much better accentuated and stronger; no murmur at apex or at epigastrium. There was, however, a strong murmur, distinctly diastolic, large and moderately harsh, heard at the third left interspace, and thence upward to the second left interspace, and more strongly across and upwards over the sternum to the second right interspace. The digitalis was continued in reduced doses. The diagnosis was made of laceration of one of the aortic valves, with probably some pre-existing disease of their tissue.

The subsequent history of the case can be briefly sketched. The patient lived over five years afterwards, and died suddenly on the 20th of September, 1873.

During this long period he never regained health sufficiently to return to work even of the lightest kind. He was able at times to walk a few squares, but much of each year was confined to the house. He suffered several times from attacks of articular and muscular rheumatism, which yielded readily to the use of opium and iodide of potassium and acetate of potassa in full doses. Usually the action of his heart was regular,—75 to 80 a minute,—and he suffered only from a sense of weight at the præcordia. But at irregular intervals he also suffered from terrible attacks of cardiac disturbance, brought on by over-exertion or occurring in connection with rheumatic fever. Then the action of the heart became tumultuous and very rapid: on repeated occasions I have counted it at 190, 200, 220, and have known it so much more rapid than this that I could not follow it at all. The heart gradually underwent enlargement, the area of dullness increasing, and the area of impulse extending, while the impulse grew heaving. The physical signs continued to indicate extensive aortic regurgitation: a loud, long, and rather hoarse diastolic murmur was heard very strongly all along the sternum, and at the second right interspace. It was equally intense at the xiphoid cartilage as at the latter point. It was transmitted also to the apex, though with rapidly lessening force. It was also transmitted along the arch of the aorta and into the great arteries; though here it lost its purely diastolic rhythm and became a prolonged bruit, occupying part of both periods of the heart's action. No other valvular murmur was heard. There was marked visible jerking pulsation of the arteries. The man's appearance was always characteristic of extreme anæmia of the arterial circulation. His surface and mucous membranes were very pale, and the pupils dilated. No symptoms of embolism presented themselves at any time. There was occasionally slight return of hæmoptysis. No enlargement of the liver or the spleen, and no albuminuria, occurred.

His treatment consisted in careful regulation of diet, clothing, and exercise. So long as the action of the heart continued regular and almost normal in frequency, he only took at intervals courses of iodide of potassium or of arsenic. Many transient disturbances of different functions also needed simple treatment. His great source of relief was, however, digitalis. On every occasion when his heart became excited and hurried in its action, a sign which was always followed by grave symptoms so soon as the pulse-rate reached 120 to 150, I placed him on the use of tincture of digitalis, in doses of ten drops every five, three, or two hours, according to the urgency of the symptoms, and then, as they subsided, gradually reduced the frequency of its administration. Its use never failed to give prompt relief. The pulse grew slower, fuller, and stronger; cardiac pain and oppression diminished. In no instance did any

disagreeable, much less any dangerous, symptom attend its action.

About the 10th of September I saw him, after a long interval caused by my absence from the city, and found him much exhausted by intense pain in the cardiac region, which had lasted several weeks. The pain was sharp and cutting, and extended round the base of the left chest, along the sternum, and through to the spine. The pulse was extremely frequent and feeble; the heart's action tumultuous, weak, and undulatory. Under the prompt use of digitalis and quinia he soon began to improve, and the amount of digitalis had been for several days reduced to five drops twice or three times a day, when, without any warning, he fell dead from his chair.

The autopsy was made twenty-four hours after death, the examination being limited to the thorax and the abdomen. There was no trace of dropsy. The liver was too firm, and presented partial nutmeg congestion. The spleen was one-half too large, its tissue too firm, with enlargement of trabeculae, but without emboli.

The kidneys were not enlarged; their capsules were thickened, but could be stripped off, bringing away a few little bits of tissue. The cortex was coarse-grained and hardened. The whole organs were much congested; there were no emboli.

The ribs were very firmly ossified. The lungs were adherent throughout; their tissues essentially healthy.

The arch of the aorta was much dilated; the entire width of the vessel when opened being about 5". Its walls were much thickened, and highly atheromatous. This condition was most marked near the heart, and gradually diminished in the abdominal aorta. The subclavians and iliacs were but slightly atheromatous. The pulmonary artery was also dilated.

The heart was much enlarged, and weighed, after careful washing, twenty-five ounces. The *right ventricle* was moderately dilated, and its walls somewhat thickened; the tricuspid valve appeared healthy. The valves of the pulmonary artery were somewhat enlarged, but healthy. The left ventricle was the seat of the greatest enlargement. Its walls were in places $\frac{3}{4}$ " thick, and its cavity much dilated. The muscular tissue was hard and reddish. The mitral valves were healthy, and stood the hydrostatic test.

On opening the aorta there appeared to be but two leaflets, one of which was somewhat larger than normal, while the other was almost twice as large. On examining this latter one more carefully, it was found to be composed of two leaflets which were fused together, their common attachment to the aortic wall having been separated along the entire line from its highest point down to the level of the base of the valves. This abnormal leaflet was quite easily reverted into the cavity of the ventricle, and would then of course have caused very great insufficiency of the aortic valves. Even when it was not so reverted, the hydrostatic test showed considerable regurgitation through that orifice. The line of the former attachment of these leaflets was marked by a Y-shaped elevation on the inner surface of the aorta. This did not altogether resemble ordinary atheroma; it was grayish-white, firm, and fibrous in texture, and seemed like the cicatrix of a branching linear ulcer or rent of the lining membrane. It had undergone none of the secondary changes (alterations of color to a yellowish tint, softening, or calcareous change) which were seen in most of the neighboring atheromatous patches. The leaflets themselves were thickened and too rigid; their ventricular surface was smooth and entirely free from vegetations, but along the arterial face of the base of attachment there were irregular calcareous formations.

In reviewing this interesting case and observing the abruptly sudden development of symptoms of

extreme aortic regurgitation, there can, I think, be felt no doubt that at the moment when the violent muscular effort was made there was a forcible separation of the leaflets from one of their lines of attachment, as above described. I have also but little doubt, considering the very advanced atheromatous changes in the aorta, and the positive symptoms of cardiac disturbance presented by the patient for a year previous, that there had been some pre-existing disease of the aorta, which impaired the consistency of its inner coats and thus favored the occurrence of the laceration.

In its clinical aspects the chief interest of the case lay in its treatment. There could be no uncertainty as to the diagnosis, since the characteristic symptoms of aortic regurgitation and the ordinary effects of the primary lesion, both upon the other parts of the heart and the system at large, were all present. The only remarkable symptom in this case was the rapidity of the pulse, which at times exceeded anything I have ever known in an adult. It is impossible to imagine a case which would illustrate more perfectly the value of digitalis in cases where the muscular walls of the ventricles are overstrained and contract feebly and frequently. Clinical experience and physiological experiment have at last definitely settled that the first and most important action of digitalis upon the heart is to increase its power of contraction. In cases like the present, therefore, where an overwhelming strain is brought upon the ventricles of the heart, under which their walls are yielding, this drug may be used fearlessly and freely. Under its action the pulse will become slower, fuller, and stronger, and the most alarming symptoms of disturbance of the circulation will subside. The amount to be given daily must depend solely upon its influence upon the heart. I rarely give more at first in any case than ten drops of a good, reliable tincture every five hours, and, if necessary, increase it gradually to every two hours; and in very few suitable cases will this fail to afford very great relief. It is true that in diseases of the aortic valves sudden death is especially liable to occur; and this tendency is strikingly illustrated by the present case. Formerly a great deal was said about the danger of using digitalis freely or for a long time, for fear of its finally producing serious or fatal depression of the circulation by its cumulative action. It is certainly true that when pushed beyond the limits of safety, and especially when given in unsuitable cases, digitalis produces dangerous depression of the circulation. Even in such cases, however, there is generally warning of the approach of danger. But in cases where its use is markedly indicated, I have never seen injurious effects from the administration, under careful watching, of ten drops of the tincture every four, three, or even two hours, until slowing of the pulse begins to be noticed, when the frequency of the dose should immediately be reduced. In the case now reported it not only produced no disagreeable effect, but it is quite certain that on repeated occasions attacks so severe that they would have proved fatal unless promptly relieved, yielded readily and safely to its action.

ORIGINAL COMMUNICATIONS.

PATHOLOGICAL DENTITION.

BY JAMES W. WHITE, M.D.

DENTITION, though a physiological process, is nevertheless recognized as a frequent cause of constitutional disturbance. Doubtless there are extremists who overestimate the average influence of this process as a disturbing element, as there are those who underrate the difficulties which may attend it. Pathological dentition is by many considered a secondary affection,—a single link in a chain of deranged actions,—and, even when a little patient indicates unmistakably the local irritation, relief is sought by general medication,—relaxants, derivatives, calmatives, febrifuges, etc.; then by local emollients, fomentations, and anodynes; and lastly, if at all, by lancing the gums, when redness, tumefaction, induration, or the whiteness of the coming tooth seems to demand it. These signs are indeed assumed to be the only possible justification of the operation. If the gums are tumid, tense, and shining, swollen up into a kind of little tumor over a particular tooth; if an unhealthy ulceration with a sloughy appearance forms upon the summit of the gum; then, say our text-books and writers upon the diseases of infancy,—then we may sometimes resort to incision of the gum.

"In forming a diagnosis," says one of the highest authorities, "whether a disease present during the time of teething is consequent upon some derangement of this process, or upon an abnormal condition of some other organ or organs of which the dental difficulty is but itself a symptom, the state of the jaws must be the principal guide. If, in the presence of symptoms which might arise from teething, we find that the teeth are not pressing forward towards the surface of the gums, and that the latter maintain their normal appearance, it will be useless to have recourse to the gum lancet." Young practitioners are cautioned, by a recent writer, not to display their ignorance by the use of the lancet, except the *local* indications imperatively demand it. The local signs, it is to be inferred, are tumefaction, redness, induration, ulceration, and the whiteness of the presenting tooth. The direct pressure upon the fibrous tissue is thus assumed to be the cause of the various and serious complications which are too frequently associated with the period of the primary dentition. It is doubtless true that a hyperæmic condition of the gums may be caused by the growth or eruption of the teeth proceeding more rapidly than does the absorption of their integumental covering, and that the undue pressure thus caused may occasion trouble, by the irritation of the nerves of the gum-tissues,—manifested locally by tumefaction, soreness, redness, or ulceration; systemically, by fever, irritability, sleeplessness, etc. It is also admitted that judicious treatment of pathological dentition should in all cases include hygienic care, and that constitutional medical, as well as local surgical, interference is generally demanded. Nor is it claimed that in the perversion of this physiological

process is to be found an explanation of all the ills to which human infancy is heir; but we assume that pain so intense and unremitting as to destroy the appetite for food, to cause wakefulness, irritability, thirst, fever, diarrhœa or constipation, congestion, convulsions, and death, may be due to the irritation of dentition *without the existence of a single local indication*. In other words, that the most serious complications of dentition are not caused by the pressure of the advancing tooth upon the gums, but by the backward pressure of the resisting gums upon the developing and sensitive *pulp*, giving rise to a true toothache, comparable only to that exquisite torture which is experienced in after-life from an exposed and irritated pulp.

If such a condition of things is possible, it will readily be seen that there can be no question as to the extent of the mischief which may result. The association of the fifth pair of nerves, which supplies the dental filaments, with the great sympathetic so connects the teeth with the entire economy that the pathological bearings of such deranged action may not be limited. That such a condition may exist will be readily understood, if it is remembered that at the period of eruption the roots of the teeth are as yet incomplete; that instead of the conical termination and minute foramen which characterize perfected teeth, the aperture is quite large, and its edges thin and sharp. In estimating, therefore, the amount of constitutional disturbance which may result because of a want of accordance between the eruption of a tooth and the absorption of the superimposed tissues which impede it, we may imagine the sensitive pulp, made up of arteries, veins, and nerves, in a condition of irritation from augmented vascular and nervous action,—a morbid activity of the process of dentition,—followed by determination, stasis, and congestion, producing a hyperæmia sufficient to cause the protrusion of the mass from the incomplete aperture of the root; which, being pressed upon by its thin, sharp edges, is sufficient cause for any amount of constitutional disturbance of which it is possible to conceive.

Under such circumstances it is not difficult to comprehend the inefficacy of any or all hygienic measures; of relaxants and febrifuges; of local emollients and anodynes. It is also easy to understand how the thorough lancing of the gums, over the tooth or teeth thus situated, may, by removal of the pressure, give a relief so immediate and complete that there shall be no room for doubt as to the correctness of the diagnosis.

The *general* indications of what may not inaptly be termed infantile odontalgia are precisely what might *a priori* be expected. The child, at first simply uneasy, becomes by rapid stages fretful, troublesome, peevish, cross, vindictive; cries persistently, or stops crying only to scream; or, if quiet for an instant, will be found to have its thumb or fingers thrust between the jaws, the chewing upon which seems to afford a momentary cessation of anguish, but only momentary. It refuses food, throws down its toys if handed to it, as though in a passion, and is outraged by any attempt to amuse

it. To these persistent unmistakable evidences of irritability are added a flushed face, corrugated brow, compressed lip, intolerance of light, and disturbed, broken sleep, the desire and effort to sleep seeming to be thwarted by fresh accessions of pain, until the little one sinks exhausted into a troubled slumber, but of short duration. Concomitant with these manifestations, or quickly succeeding them, will be some of the various systemic complications, too frequently with fatal ending, and still *no local indication* of the trouble which is consuming the young life.

A case recently under the care of the writer afforded a marked confirmation of these views. A child one year of age, with the four superior and two inferior incisors in position, after three weeks of restlessness, wakefulness, loss of appetite, fever, paroxysms of pain, and rapid emaciation,—all without obvious cause, certainly without the slightest local indication of trouble in the mouth,—was *cured* by free crucial incisions over the molar teeth, the improvement being so evidently the result of the operation that the relation of cause and effect was plainly recognized by every member of the family.

Such cases are not exceptional, and suggest a more careful investigation of the developmental processes of dentition in otherwise unexplainable diseases of infancy.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. R. J. LEVIS.

Reported by JOHN B. ROBERTS.

ANEURISM OF THE SUBCLAVIAN ARTERY.

JAMES M., aged 41 years, was admitted with a large aneurism of the right subclavian artery, which has been recognized only about three weeks previously to his applying at the hospital for treatment. It has evidently existed much longer, however, for he has complained of pain in the right chest and down the arm for nine months, and the clubbed fingers of the right hand show conclusively that the tumor has acted for a long time as an impediment to the return of venous blood.

A pulsating tumor, with distinct aneurismal thrill, is seen jutting above the clavicle, and below that bone another swelling is felt, in which the thrill, however, is almost absent. It is difficult to determine whether this lower tumor, below the clavicle, is a portion of a large aneurismal sac bulging out between the first and second ribs, or a dilatation in the continuity of the vessel as it becomes axillary, after it has passed under the clavicle; in other words, whether the aneurism is entirely subclavian and intra-thoracic, or involves the subclavian and its axillary continuation. The aneurism certainly includes the entire subclavian artery, and probably a portion of the axillary, but how far it extends towards the heart is uncertain, for there may be some dilatation of the innominate, although the primitive carotid seems to be normal.

Aneurisms, when not traumatic, are the result, usually, of atheromatous change in the arterial coats, which so interferes with the contractility and nutrition of the vessel that atrophy takes place. The weakened

coats are then dilated by the constant pressure of the blood, until an aneurismal sac is formed, or rupture takes place from a sudden increase of intravascular tension by excessive emotion or severe exertion. In the treatment of aneurism it is of great importance to consider the extent to which this process has advanced; for the surgeon must be influenced in the choice of operative procedures by the condition of the coats of the artery.

The cure of aneurism depends on the formation of a clot in the sac by deposition of fibrin from the blood; and accordingly many methods have been suggested to produce this result. One of the oldest plans of treatment is ligation, by which the current blood is arrested and an opportunity given for lamination of fibrin to fill up the cavity of the sac.

The ligature may be applied upon the vessel far above the tumor, as first performed by Hunter, or below it, as in the distal operation suggested by Brasdor; in either of which cases it is necessary to select, as certainly as possible, a portion of the vessel free from disease.

In this patient the Hunterian operation is impracticable, for, as the tumor involves the entire subclavian, the ligature would have to be placed around the innominate artery, which lies deep in the neck behind the upper bone of the sternum, and has large venous surroundings. A most important objection, moreover, is the fact that the innominate is so short and gives off such large branches that there is not room for a firm clot to form, as was shown in the only successful ligation of this artery, where the additional ligation of the vertebral was necessitated.

The distal operation upon the axillary is, therefore, the one to be adopted in this case, if it be decided to trust to ligation; but an objection is that should the vessel be atheromatous, and secondary hemorrhage supervene, there would remain no point higher up to which a ligature might be applied. The ligation of the carotid also would probably be required, for the aneurism extends so near to the bifurcation of the innominate into the subclavian and the carotid that the current in the latter would interfere with fibrinous deposition in the sac.

Partial and complete compression have also been resorted to for the cure of aneurism, depending for their efficacy in diminishing or entirely arresting the circulation and allowing a deposit of fibrin.

In a case of internal iliac aneurism in the hospital, Dr. Levis succeeded in effecting cure by *complete* or rapid compression upon the cardiac side of the tumor for five hours and twenty-five minutes. This plan has of late become quite popular, being particularly adapted to treatment of aneurism of the abdominal aorta and other large arteries, for it produces complete stasis of the blood, and, if anæsthesia be kept up, is unattended with great suffering.

As spontaneous coagulation occasionally takes place in the dilatation, attempts have been made to accomplish this by the injection subcutaneously into the sac of tannic acid, subsulphate of iron, and other astringent solutions. These efforts have been attended with at least some degree of success; but the clot generally sets up a high inflammation by acting as a foreign body. Many other methods have been tried, among which may be mentioned violent manipulation of the tumor in order to detach the fibrinous laminæ usually adherent to the inner walls of the sac, so that some of the detached material may plug up the distal extremity of the aneurism and stop the current of blood.

It has occurred to Dr. Levis that coagulation might be induced by introducing into the cavity of the aneurism, through a capillary tube, a number of horse-hairs

one after the other, which, by acting as remora on the blood passing through them, would entangle upon them a large quantity of fibrin; and it is his intention to attempt the radical cure of aneurism of the great arterial trunks of the thorax and abdomen by this means in cases which are not amenable to treatment by the usual operative methods of ligature or compression.

This subclavian aneurism is perceptibly increasing, and it will continue to dilate until it bursts into the pleural cavity, the trachea, the œsophagus, or the subclavian vein, if not soon successfully treated; but at present nothing will be done, except to place the man on a good *nitrogenous* diet, in order to increase, if possible, the quantity of fibrin in the blood; and to tranquillize the circulation by digitalis and the recumbent position.

In the mean time the most careful physical exploration of the extent of the aneurism and its possible complications will be made, and serious consideration given to means for relief from a condition in which, sooner or later, a fatal termination must otherwise be expected.

CASES OF OVARIOTOMY.

BY WASHINGTON L. ATLEE, M.D.,

Of Philadelphia.

Reported by J. EWING MEARS, M.D., of Philadelphia.

CASE 246.—*Multilocular ovarian tumor—Incision five inches in length—Slight parietal adhesions—Recovery.*

December 13, 1871, Dr. Atlee visited Miss E. B., of Schenectady, New York, in consultation with Dr. A. M. Vedder. The patient was 46 years of age, a teacher by profession, and, until October, 1871, had enjoyed general good health. Menstruation began at the age of sixteen, and has, at times, been irregular and excessive. In August, 1871, she noticed that her dresses were getting tight, and she suffered somewhat from dyspnœa; œdema of the lower extremities was also present.

Previous to the time when Dr. Vedder took charge of the patient, she had been treated with drastic purgatives, and had been rigidly confined to bed.

On examination, Dr. Atlee found the abdomen as large as is usual at full term of pregnancy, and quite uniform in shape. There was resonance on percussion over the right lumbar region and the upper border of the abdomen; at all other points dulness on percussion was marked. The abdomen was tense; several hard masses could be felt on palpation, occupying chiefly the umbilical and left lumbar regions. Fluctuation was imperfect, being more distinct in the right lumbar region. The pelvis was free, the uterus was central in position, and the cervix was normal. The sound could not be introduced; the tumor could not be moved by deep inspirations. The diagnosis of multilocular tumor of the left ovary, with parietal adhesions, was made.

Ovariectomy was performed, the following gentlemen being present: Drs. A. M. Vedder, J. D. Jones, R. M. Fuller, M. G. Plank, B. N. Myndevre, Pease, Niles, and F. Ellwood, of Schenectady, and G. S. Beckwith, of Charleston, N.Y.

The tumor involved the left ovary, was multilocular in character, and was attached to the anterior wall of the abdomen by adhesions which were easily detached. The pedicle was of good length, and was secured by a three-quarter inch Atlee clamp. The patient made a very satisfactory recovery, although she suffered from bedsores which resulted from long confinement in bed in one position previous to the operation.

TRANSLATIONS.

TRACHEOTOMY BY THE ACTUAL CAUTERY.

By MM. F. DE RANSE and MURON. Translated from the *Gazette Médicale*, No. 38,

BY GEORGE S. GERHARD, M.D.

THE interest with which we listened to the subject of tracheotomy by the actual cautery, communicated to the Société de Médecine by M. de Saint-Germain, led us to institute some experiments, the results of which we are now able to record. The object of employing the actual cautery in tracheotomy is to prevent hemorrhage, and thus to do away with one of the principal difficulties with which the surgeon has to contend.

There are a certain number of cases in which hemorrhage occurs on the first incision to such an extent as to mask and render more delicate the subsequent steps of the operation.

The actual cautery is simply a substitute for the galvano-cautery, which has been employed by M. Verneuil in tracheotomy. The priority of performing the operation, therefore, belongs to the eminent professor; and if we prefer the actual cautery to the galvano-cautery it is because the latter is not in the hands of every surgeon.

We think that the actual cautery, by preventing hemorrhage, will render the operation of tracheotomy more simple, and that a physician who formerly recoiled from its performance will now no longer hesitate to attempt it.

For these reasons we propose to give in detail the different steps of the operation as we performed it upon animals (dogs).

The first question which presents itself concerns the choice of instruments. At first we employed an ordinary table-knife with a rounded end; but afterwards we had a very small instrument made by Mr. Cohn, which divided the tissues only so far down as the trachea. A table-knife is undoubtedly the most practicable, because it is so easily obtained; the only objection to it is that its extremity is sometimes so thin that the skin and cellular tissue are divided too slowly, and the former as a consequence becomes cauterized to an unnecessary extent. If, however, a knife with a stout extremity be selected, an immediate division of the tissues will be effected without cauterizing the skin beyond the cut.

To completely divide the tissues as far down as the trachea, two table-knives are generally sufficient; but, in order to be prepared for any accident that may happen, we think it prudent to be furnished with three or four.

The extremity of the knife, having been heated bright red to an extent of two centimetres, should be applied firmly to the skin at a point one centimetre below the cricoid cartilage, and held steadily, lest too large a wound be made.

The instrument we prefer consists of a flattened elliptical piece of iron supported by a handle seven or eight centimetres long; the latter has a roughened extremity, so that it may be tightly held by a pair of forceps. The cautery is irregularly elliptical, one end being larger than the other, and is, therefore, readily adapted to the age of the patient. The cautery, having been heated bright red, is firmly held by a pair of forceps, and when the patient's head has been extended the larger end of the instrument is applied to the skin at the point before indicated, below the cricoid cartilage. It is important to stretch the tissues at the moment of the application, in order to facilitate their section. The skin and the subcutaneous cellular tissue are thus rapidly divided.

Separating the edges of the wound with a pair of ordinarily strong forceps, and returning the cautery, which has cooled considerably, the aponeurosis and all other tissues are divided, and the trachea is brought to view. So soon as the trachea is exposed, we think it advisable to withdraw the cautery, for fear of denuding the cartilages and causing necrosis.

Separating the divided tissues with the same pair of forceps, the trachea is divided with a bistoury. The edges of the tracheal wound are separated by means of a Laborde dilator, along the inferior branch of which a canula is readily made to pass. We heat the cautery to a cherry-red color because the skin and the cellular tissue are thereby more rapidly divided,—a result which is not attended by any bad consequences, because the vessels of these tissues are not large enough to give rise to hemorrhage. During the first step of the operation the cautery cools, and when the more deeply-seated tissues are about to be divided the obliteration of the vessels is certain.

We stated at the commencement that the object of the operation by the actual cautery was to prevent hemorrhage; let us see if this end is always attained. In twenty-two operations upon dogs, hemorrhage occurred but twice; in all other instances the tissues were perfectly dry, and at the bottom of the wound the trachea could be distinctly seen. The slight hemorrhage that occurred in two cases was due to our attempting to divide too great an amount of tissue with the same part of the instrument; the vessels were divided, but the cautery was not hot enough to obliterate them completely. An important point to be borne in mind, after dividing the skin and the cellular tissue, is to employ the smaller and thicker end of the instrument in dividing the more deeply-seated tissues. In no instance, when this precaution was taken, did hemorrhage occur.

In addition to the complication from hemorrhage, which, as we have already stated, is easily prevented, we ought to mention another, consisting in a partial necrosis of one or two cartilages of the trachea and causing eventually slight stricture. The danger of the occurrence of necrosis may be easily avoided. The cautery divides all that it encounters: when it reaches the trachea it meets with a certain resistance, but the perichondrium may be destroyed, and as a consequence a disturbance of nutrition occurs, resulting in partial necrosis. As we have already stated, we should, so soon as the trachea is exposed, withdraw the instrument and employ the bistoury.

RESEARCHES ON PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.

By BERGER (*Deutsches Arch. für klin. Med.*, 1872, Bd. ix., Heft 4, 5).
Translated from *Archives Générales de Médecine*, Août, 1873.

By ENRIQUE M. ESTRAZULAS, M.D.

IN the cases of this disease studied by Berger, new features are added to the train of symptoms usually recognized as belonging to it, and consisting of various troubles of sensibility. These troubles are of hyperæsthesia and anæsthesia relating to the various modes of sensibility,—tact, thermæsthesia, pain. He maintains that the disease always begins in the lower extremities, being generally accompanied by violent neuralgic pains and formication in the affected muscles. Later this gives place to anæsthesia. Also, he has found that fibrillar contractions are of constant occurrence.

The enlargement of the paralyzed muscles is, according to Duchenne, due to hypertrophy of the interstitial connective tissue, the muscular fibre remaining normal, or becoming atrophied afterwards by the compression exerted by the hyperplasia of connective tissue.

In two cases where the author had an opportunity of examining the muscles microscopically, he found a complete absence of proliferation and of fatty degeneration in the interstitial connective tissue, and a true hypertrophy of the muscular fibril,—hypertrophy so developed as to account by itself alone for the development and enlargement of the limb.

The author is far from denying the correctness of Duchenne's microscopical researches, but he thinks that the latter has observed the disease at different periods from himself. Berger has studied it at the beginning, and found a true hypertrophy of the muscular fibril, and later (and here he agrees with Duchenne's observations) the connective tissue begins to proliferate and in turn hypertrophies, thus compressing the muscular fibre and occasioning its atrophy.

There are, then, two anatomical stages to be recognized in the disease,—the first characterized by a true muscular hypertrophy, and the second by a hypertrophy of the interstitial connective tissue and the subsequent atrophy of the muscular substance. The first stage is clinically marked by neuralgia, hyperæsthesia, and anæsthesia, and afterwards feebleness, but not abolition of motility; the second, by true paralysis, in company with considerable increased volume of the affected muscle.

The author then reviews the different hypotheses that have been advanced in regard to the nature of the disease. Duchenne attributes it to a paralysis of the vaso-motor nerves; Stofella, to a cerebral lesion; Gneisinger, to a primitive muscular lesion; but according to Berger the muscular alteration is not due to a trouble of the vaso-motor nerves, but to a trouble of the trophic nerves. The trophic nerves destined to a muscle appear not to follow the track of the motor nerves, but that of the sensitive ones, and hence the frequency of troubles of sensibility accompanying the trophic lesions of the muscles.

The trophic nerves probably act as moderators of the nutrition of elements, since their destruction is followed by an irregular and exaggerated hypertrophy of the elements they supply, and the atrophy only comes later after a lapse of time more or less long. In conclusion, Berger believes himself authorized to place the pseudo-hypertrophic paralysis among the muscular tropho-neoroses.

DEATH FOLLOWING THE EMPLOYMENT OF THE STOMACH-PUMP.

Translated from the *Gazette Hebdomadaire*, September 26, 1873,

By GEORGE S. GERHARD, M.D.

AN inquest was made on the 21st inst. on the body of a man fifty years of age. It appears that the deceased, who had been intemperate, was in the habit of taking every day an ounce of tincture of rhubarb as a stimulant. At seven o'clock on the morning of the 16th of August he went to the apothecary for his accustomed dose, but after having swallowed it he observed that it had an unusual taste. The apothecary, finding that he had given laudanum to the patient instead of tincture of rhubarb, at once administered an emetic dose of sulphate of zinc. One physician who was summoned gave three pints of warm water, and another proceeded to the use of the stomach-pump, but the tube first employed was too large, and a smaller one also failed to pass. Ten grains of sulphate of zinc were administered, with the effect of producing copious vomiting, but the patient died three days afterwards, without having presented a single symptom of narcotic poisoning. He complained of pain in the throat, and was unable to swallow. At the autopsy there was found a

stricture of the œsophagus, probably of a malignant nature, which explained why the tube failed to pass. Above the seat of stricture the œsophageal wall, which was very thin at this point, was found to have been perforated by the tube. The patient, before the accident, had not presented any symptoms of stricture of the œsophagus. The jury exonerated the two physicians from all blame, and rendered a verdict of accidental death; they considered the druggist, however, as meriting grave censure.

We think that the case in point should not be brought up as an argument against the use of the stomach-pump when it seems to be clearly indicated. No one would think of employing the instrument when a stricture of the œsophagus was known to exist.

The case should teach us to be on our guard when we are using this instrument in cases of poisoning. We, however, believe that the unexpected discovery of a stricture of the œsophagus in one who has been poisoned is of as rare occurrence as the indication for the emptying of the stomach by means of the pump; for, according to our experience, there have been but few lives saved by the operation.

ELIMINATION OF MERCURY.

DRS. MAYENÇON and Bergeret, in a study of the action of mercury (*Journal de l'Anatomie*), found that when one centigramme of the bichloride was injected hypodermically into a dog the metal was to be found in the urine during the following twenty-four hours; when a centigramme was administered during ten or twelve days, the urine contained mercury during the whole time and for four or five days afterwards. They failed to find it in the saliva but did detect it in the spermatic fluid of an embosser. In a ptyalized nursing woman the milk contained as much as the saliva; and the authors detected the drug in the urine of a baby fed at the breast of a mercurialized female.

In a second series of experiments, rabbits were killed at various intervals after the injection of a solution of the bichloride, and their tissues examined. It was found that in half an hour the drug had permeated everywhere, but was most abundant in the liver and kidneys. In four days the mercury given in a single dose was all eliminated, and could not be found in the tissues. By the continuous use of the metal it certainly accumulates and remains in the system. Thus, neither the urine nor the blood of one of the investigators contained any of the metal forty-eight hours after the cessation of a mercurial course. Yet, on taking iodide of potassium, mercury reappeared in the urine, and continued to be present for forty-eight hours.

LANCING THE GUMS (*The Dental Cosmos*, February and March, 1873).—Dr. J. Foster Flagg gives the following practical directions for an operation which is too often imperfectly and unskillfully performed. Until recently it has been thought sufficient to make a single straight incision over the coming tooth, and in many instances the mucous membrane has merely been scratched with the point of the lancet; there has been no relief of tension and inflammation, and in not a few cases the result has been fatal.

In making an examination of the gums of an infant over ten months old, the finger should be introduced at the front of the mouth, as thus, the centrals, and usually the laterals also, being fully erupted, all contact with tenderness is avoided. Under the age of ten months the corner of the mouth should be selected. The lancet should be wrapped with a piece of tape, beginning about a quarter of an inch from the point,

and covering the remainder of the blade and a portion of the handle, securing it by slipping the end of the tape under the last turn and drawing it tight. This having been done, that portion of the gum which covers the irritating tooth should be taken gently between the first two fingers of the left hand, the thumb steadying the jaw by resting under the chin or upon the cheek, as thus, in any part of the mouth, the tongue, lips, and cheeks are protected. The incision should be made slowly, steadily, carefully, and gently, passing through the gum until the enamel of the coming tooth is felt, but *only felt*, as this tissue is yet not so hard but that it might possibly be injured by undue force in cutting.

UPPER JAW.

LOWER JAW.

In lancing for the centrals and laterals of both upper and lower jaws, the incisions should be made nearly over the cutting edges of those teeth, but, while the cuts in the upper jaw should be made rather exteriorly to the centre of the alveolar ridge, those of the lower jaw should be made inside of the centre. The single cut over the cutting edge removes, practically, all impediment to complete eruption, for as the teeth become thicker in one direction they become narrower in the other. The object in lancing a little externally above and a little internally below is to offer pathways to the teeth, which shall tend to favor the production of

the normal occlusion by guiding the upper teeth outwardly and the lower ones inwardly.

The first molars (twelve-months teeth) should always be lanced with cervical incisions at least; but a more decided difference exists between those of the upper jaw and those of the lower than between any of the other teeth thus compared. In the upper jaw the cervical incision, as delineated in the diagram, relieves tension over the most prominent points of these teeth,—the buccal and palatal cusps,—while in the corresponding teeth of the lower jaw we should employ the crucial incision, thus, X, because in this way we reach their most prominent points,—the two mesial and two distal cusps.

FOREIGN BODY IN THE CÆSOPHAGUS (*New York Medical Review*, September, 1873).—Dr. D. E. Smith relates the case of a young married woman, who, during an attack of puerperal convulsions, swallowed a partial set of false teeth, four in number, and fastened with a gold clasp. They remained for three days in the pharynx, which was not examined by the attending physician, who declared it to be impossible that the teeth could have been swallowed. At the end of this time, her ingesta having in the mean while been completely fluid, she ate a small piece of beef-steak, in company with which the teeth passed down the œsophagus to a point near the cardiac orifice, where they were arrested by the hook of the clasp penetrating the œsophageal wall. The patient remained in this condition for three months, gradually growing weaker, and undergoing treatment for indigestion, general debility, incipient phthisis, etc., her physician persistently denying the presence of the teeth. A post-mortem examination disclosed the facts to be as above related.

PHILADELPHIA
MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 25, 1873.

EDITORIAL.

ETHER AS AN ANÆSTHETIC.

SOME years since, a friend of ours, when on a visit to an English homestead, as he went to dinner was amused by seeing the children peering at him from behind the door, and by hearing one of them say, "Why, he ain't black!" We had thought this purposed ignorance of the existence of America—this purposed ignorance of it and its people—had been battered down by the events of our late war and by our achievements in the arts and sciences. But a London fog is a hard thing to get light through; and in a recent article in the *Edinburgh Medical Journal* Dr. Charles Kidd does battle for the rights of chloroform in a manner worthy of the former time and of his ancient namesake of buccaneering fame. "One or two Americans," he tells us, "have, with an allowable national pride, set up ether as the one thing necessary to save all medical men from ruin; they would abolish chloroform by special act of Parliament, and, as done in America, expel any surgeon from an hospital who would use chloroform in place of the American anæsthetic."

Again he informs us, "To help out this weak agitation, it is shown that, by some American specialty, ether is far preferable; and to men who are ready to advertise the specialty of some American hair-wash, some sewing-machine, or substitute for tea, that chloroform is terribly homicidal, and with an apparatus special, ether, as in America, for what they know, has not had one death; and in France,

at Lyons, the same magic halo of perfect safety has surrounded it: both these latter statements are altogether misleading and erroneous."

Let us, in the first place, assure Dr. Kidd that it is not one or two physicians, but the great bulk of the American profession who stamp the indiscriminate anæsthetic use of chloroform as homicidal; and let us say to him also that, if good taste do not lead him to speak respectfully of his transatlantic brethren, a care for his own reputation ought to induce him to pay some attention to the habits of even such a wild animal as an American before he comments upon them in print and writes such nonsense as that a hospital surgeon would be expelled here for using chloroform. The doctor seems, however, to set little store by his reputation, for he is as reckless in regard to the construction of his sentences and the truth of his asserted facts as to the canons of good taste. The last sentence we have quoted will serve as an example of the preciseness of his style: we leave it to our readers if they can form any idea as to what is meant by ether being "far preferable by some American specialty."

As an example of his scrupulous care in regard to the accuracy of his statements may be cited the following sentence: "The well-known seven deaths at Lyons, and forty-one of the Boston committee, all from ether, are, from insufficient knowledge, forgotten or misrepresented." The real truth is that the Boston committee reported that forty-one deaths had been attributed to ether, but that in many of them to lay the credit of the fatal result to the anæsthetic was simply absurd, and that there was "no recorded case of death known to the committee, attributed to sulphuric ether, which cannot be explained on some other ground equally plausible, or in which, if it were possible to repeat the experiment, insensibility could not have been produced and death avoided."

As the death-roll of chloroform—shall we say?—murders grows day by day,—as even English coroners and English magistrates are becoming restive under the slaughter of the people,—as doctor after doctor, having claimed that his method of using chloroform was safe, is forced to own by bitter experience that he is not, after all, so much more skilful than his fellows,—as these things are so, it seems to us strange that any one should still come forward and practically say, "I hold the giant powers of chloroform for evil, as it were, in the hollow of my hand. Its fatal spirit is bound at my bidding; no death shall occur when I direct."

In view of the various events in the history of chloroform, which must be in the memory of all

our readers, it seems to us nonsense to assert that deaths from it can be avoided by *any* precautions or by *any* skill. The great difference between the two anæsthetics lies in the circumstance that chloroform kills suddenly, unexpectedly, and unpreventably, whilst the ether death is a slow one, and can be avoided, unless in the very rarest of instances. The unrecorded, unnumbered dead from chloroform, our experience leads us to think, are a much greater multitude than is commonly believed. So far as we know, no case of death from chloroform occurring in this city has been recorded; yet we have known of the occurrence of several within a comparatively short time.

A NEW OPERATION FOR ANEURISM.

ON Monday, October 13, Dr. R. J. Levis performed, at the Pennsylvania Hospital, an operation so novel in its conception, so plausible in its theory, and, if it turn out successful, so important in its power of saving life, that it seems worthy of editorial notice. The case was one of subclavian aneurism, involving, it is believed at least to the extent of dilatation, the innominate. Tying the artery has been thought by the surgeons who have examined the case to be of more than doubtful expediency, and Dr. Levis has carried out a procedure which he tells us has long been in his mind. As every one knows, the late Charles H. Moore, surgeon to the Middlesex Hospital, conceived and put into execution the idea of introducing fine iron wire into aneurisms, to afford a nucleus about which clots should form. His practice has been followed in two cases, by Dr. Donville and Mr. Murray, both English surgeons. If we remember aright, in each of these instances the aorta was the artery involved, and the result was unfavorable.

Dr. Levis's idea consists in the use of horse-hair, with the belief or expectation that it will offer sufficient obstacle to the blood-current to cause coagulation, and at the same time, being animal in its nature and not apt to undergo rapid decomposition, like the catgut ligature will cause no irritation and not give rise to suppuration.

The horse-hair was introduced through a fine sharp needle canula, which was plunged into the sac. No difficulty was experienced in its introduction, and twenty-four feet nine inches of it were safely stowed away in the aneurism. In all probability this mass was driven in great part into the distal portion of the aneurism by the blood-current. Be this as it may, a marked diminution in the force

of the pulsation of the aneurism and of the pulse of the wrist was at once induced. This has increased since the operation, the tumor has also gained greatly in solidity, the pain has lessened very much, and no unfavorable symptoms have resulted. As, on the other hand, the radial pulse and the aneurismal throb have never disappeared entirely, and as the dangers of suppuration of the sac are not yet past, it is too early to predict the result.

LEADING ARTICLES.

DYSIDROSIS—RETENTION OF SWEAT.

DR. TILBURY FOX, of London, gives a clinical lecture in the *British Medical Journal* for September 27, 1873, which seems to illustrate clearly the disease which he has recently described under the name of dysidrosis.

The patient was a woman, 36 years of age, and in poor health. Both hands, forearms, and arms were affected with the cutaneous disease. Dr. Fox describes the condition as follows:

"There are scattered papules, which, on close examination, are seen to be in reality vesicles; and also very distinct vesicles, of the size of millet-seeds, some of them having a red base, and in some cases being crowded together in little groups, more or less scattered all over the backs and sides of the fingers, and the back and front of the hand, and the whole forearm (back and front), and the arm up to the shoulder, especially its inner aspect. In some cases the vesicles have run together, so as to form minute bullæ; on pricking these bullæ, a drop of very clear fluid exudes, and it is alkaline. Between the fingers the cuticle is in some cases raised slightly by a layer of fluid beneath. It is white and macerated, especially at the web of the fingers; and the fluid is faintly acid; it is also offensive. There are no crusts anywhere. On the palmar aspect there are scattered, isolated vesicles about the fingers, and towards their tips a number of minute transparent points, resembling sago-grains, are visible under the skin,—some thirty or more. These points are not raised, but are seen through the cuticle, and are clearly sweat-follicles distended with sweat. The front of the arm appears as if it were the seat of diffused eczema. The fluid contained in the vesicles remains perfectly clear until it dries away or escapes, when the cuticle shrivels and peels off or macerates. The patient complains greatly of a burning about the eruption."

Dr. Fox remarks that the affection should not be

confounded with acute eczema, erythema papulatum, miliaria, sudamina, or hydroa. Local treatment is of little avail, except to moderate the irritability and inflammation of the skin. Diuretics and tonics are to be relied upon. Dr. Fox adds,—

"I have termed the disease dysidrosis, because nature seems to have a difficulty in getting rid of the secreted sweat, which remains to distend the follicles and to macerate the tissues. The disease is nothing more than retention of sweat, and its results. Dysidrosis bears the same relation to the sweat-glands that acne does to the sebaceous glands."

L. A. D.

REVIEWS AND BOOK NOTICES.

A SYSTEM OF MIDWIFERY: INCLUDING THE DISEASES OF PREGNANCY AND THE PUERPERAL STATE. By WILLIAM LEISHMAN, M.D.

The author's object in this work, he tells us, is "to furnish to students and practitioners a complete system of midwifery of the present day." The need of such a book, we are informed in the preface, is great, since "in our language scarcely a modern work exists which can be compared with those of Cazeaux and Scanzoni." To this statement we might more readily assent were the magnificent volume of the late Professor Hodge written in a foreign tongue; but, as it exists in our own, it fills, to-day, as completely its place as a text-book of obstetrics as any text-book extant in any of the allied branches of medical science. Whether the work of Professor Leishman be worthy of a similar high rank we will now consider.

First, as to the author's qualifications for the task, we have, quoting still from the preface, the statement that "there are few modern works of approved merit, whether British or foreign, with which the author has not made himself familiar." This claim a perusal of the work proves true. It would be almost impossible to expect familiarity with all the medical ephemera and fugitive literature which to-day meet the eye at every turn, but we can safely say that we know not where in any system of obstetrics to find a compendium so full and so entirely up to the knowledge of the day. The author has added to research the attraction of a singularly graceful and easy style, a clear manner and method, good illustrations, and excellent typography. The illustrations are more than good,—they are remarkably good and pertinent. Especially would we commend those illustrating the position of the head in the different stages of delivery, as on page 327. The wood-cuts, generally, are fresh, and, though at times familiar, are acknowledged; and to borrow another author's illustration with courtesy is rather to honor him than the reverse. The work is in one volume—eight hundred and thirty-five pages quarto; containing forty-five chapters, over one hundred and seventy wood-cuts, and a good index. An enumeration of its table of contents would alone give a correct idea of its fulness and completeness. Purposely, the statistical element has been omitted, and, we think, wisely. While occasionally the views of the author do not coincide with those of many, he can rarely be convicted of ignorance of anything concerning his subject. His description of the mechanism of natural labor is wonderfully clear, though his enumerated positions of the fœtus are at variance with those

generally taught in this country, and those of many continental writers.

They are the four of Nægele, all in the oblique diameters, ignoring the four additional positions in the antero-posterior and transverse. His description of mechanism varies from the commonly taught doctrine. We see no reason to doubt its accuracy, and none at all its intelligibility. He urges the very great importance to the practitioner of early acquiring the tactus eruditus, saying only too truly that where not *early* learned it is often *never* learned; and his directions for making a diagnosis of the position of the head strike us as superior to any we have ever read or heard, so easily remembered and simple are they.

The author discards support of the perineum, and retains the binder, to support the relaxed abdomen and uterus and to preserve the figure, though he does not give as a reason for its use the very important one were all other reasons wanting,—viz., the feeling of comfort which it gives to almost every lying-in woman.

Occasionally the author is funny, as on page 309, where, in speaking of the termination of natural labor, he says, "A single glass of sherry or claret with water may be allowed; but it is truly astonishing how seldom this is necessary." When we think of the condition of parturients in certain sections of our favored land where total abstinence is enforced, we are thankful that it is so, but by no means so astonished as our author.

The author's chapters on the forceps (page 515) are inferior to most of the work, though he evidently has no suspicion of it himself. They may mark an advance in British instrumental delivery, but as a system of teaching they are not equal to our own. Beginning with a history of the invention and describing varieties of the instrument, he gives the indications for its use, and directions for the application of the blades. His personal predilection is for a straight forceps, made somewhat longer than the ordinary straight forceps, being nine inches from the lock to the tips of the blades. These, which are described in the text as straight, are figured in the wood-cut illustrating their application with a decided pelvic curve, probably out of deference to the views of those who object to the straight instrument, and are considered applicable to any case where on introduction the lock is external to the vulva. The author advocates the use of the forceps within the uterus if necessary, saying very truly that "to wait until the lips of the os can no longer be felt is to wait for what may possibly never occur." The necessity of feeling the ear before applying the forceps he considers needful only where a large caput succedaneum has obliterated our landmarks on the cranium, and adds, "But to accept this as a rule for our guidance in every case is both unnecessary and unjustifiable, as the ear, in some cases in which we may hold the operation perfectly justifiable, can only be reached with difficulty or with an amount of violence which may greatly aggravate the sufferings of the patient."

In regard to the method of applying the blades the author's trumpet appears to give a somewhat uncertain though melodious sound. "If possible," he says (page 523), "the blades should be applied to the sides of the child's head. To do this with accuracy, it is necessary that the actual position of the head be made out with perfect certainty. . . . And as there are four possible cranial positions, we must first be sure with which of them we have to deal before we ever take the instrument into our hands. . . . The method of application will depend upon the situation of the head: . . . the nearer it is to the outlet, the more will we require to apply the blades in the transverse diameter of the pelvis. Where, however, the head is higher, its position is more decidedly oblique, and even at the outlet a little of the obliquity still obtains; so that, to *insure*

their application to the sides of the head [our italics], we must apply them," etc. etc. The author then describes the situation: patient on her left side, hips to the edge of the bed; then the administration of chloroform,—evidently considering it as necessary as the previously described warming and greasing of the blades. (The author considers ether, by the way, as dangerous in midwifery, as he believes it induces hemorrhage.) Then (page 526), after describing the method of introduction and reaching the difficulty of locking the blades, he says, "Should this occur repeatedly after partial removal and introduction, it may be advisable to withdraw the lower blade and introduce it with reference to the other, as there is a possibility of a mistake having been committed as to the position of the head, and it is, besides, a matter of far greater importance to have the blades exactly opposite to each other than to have them accurately adapted to the transverse diameter of the head. The best test of a proper application of the forceps is the perfect locking of the blades after their introduction." This is certainly a long way off from the previously quoted advice; and why need a diagnosis be made at all beforehand, if the best test is so easily obtained, and perfect locking by no means implies adjustment to the sides of the head? The writer, in using an instrument very similar to that figured by the author, has succeeded many times in easily locking though the blades were by no means symmetrically applied.

The author, his blades being locked, advises the use both of traction and leverage,—“a swaying movement of the hands.” Using the instrument that he does, he cannot make use of that downward pressure upon the lock which is so valuable in forceps of the Hodge pattern.

Timidity in the use of the forceps characterizes the chapter.

On page 529 we find the following: “This leads us to observe that, if practicable, the assistance of another practitioner should always be obtained,”—advice which we look for in vain in reading the chapter on Embryotomy. Again, page 534, “No one should under any circumstances take the long forceps into his hands without a sense of responsibility much greater than attaches to the ordinary operation.” In fact, the two chapters abound in little touches not at all calculated to steady the arm or reassure the mind of the inexperienced operator. In regard to the long forceps the author entirely gives up all idea of application to the sides of the head. These forceps he describes as the so-called Simpson forceps, with loose locks, and a length of ten and one-half inches from lock to tip. Page 536: “Our object, then,” in using the long forceps, “is not . . . to secure their application to the sides of the cranium, but rather to introduce them with special reference to the pelvic walls.” These forceps also are applied with the patient in the usual obstetric position. In regard to locking, he here also regards it, if perfect, as proof enough of proper application. “But if, on the contrary, we do not succeed in introducing and locking the blades after one or two attempts carefully conducted, we must abandon the case as one unsuitable for the operation.” By this we understand the author to mean, Abandon the forceps—not the case—for some other means of relief; which to us appears like giving up too easily, and too readily falling back upon—we presume, that favorite resort in the United Kingdom—craniotomy and its perils.

Space forbids further remark; but we are convinced that Dr. Leishman's book is destined to become a favorite with all who read it. Chapters and pages like those last noticed—and they are very few—are lost in the many undoubted merits of the work, which we presume will soon appear in reprint in this country. It is to be hoped that the volume will have the advantage of a

careful editor, that it may be made to conform in a few respects with the ideas and customs in vogue upon this side the Atlantic.

SELECTIONS.

ALBUMINOUS EXPECTORATION.

I.

A VERY lively and very long-drawn-out discussion on this subject has occupied a good deal of the time of some of the societies, and of the space of most of the medical journals, of France, since the beginning of the year. The debate appears to be drawing to a close; and we avail ourselves of a spirited summary by M. Labbé in the *Mouvement Médical*, to give our readers a review of what has been said and written on the matter.

A tout seigneur tout honneur. M. Terrillon, last March, defended an unusually good and interesting thesis on the *Albuminous Expectorations following Thoracentesis*. He is the cause of all the commotion; armed by twenty-one observations, of which six are unpublished, he started the debate. He did not wish, he said, in any way to attack the favorable position of thoracentesis; his aim was to draw attention to that phenomenon which M. Pinault was the first to point out in his thesis in 1853, in which he sought to arrive at its rational explanation. In 1869, M. d'Espine communicated to the Société de Biologie two instances of abundant serous expectoration following thoracentesis. In 1872, M. Woillez, in his clinical treatise on acute affections of the respiratory organs, quoted observations of this kind (pp. 4, 8, *et seq.*). M. Marrotte, on May 22, and M. Béhier, on July 30, communicated to the Academy of Medicine facts on the subject worthy of attention.

It will be well to examine *seriatim*, by the light of this discussion, the symptoms and kinds of expectoration which ensue after thoracentesis: the origin of the expectoration, its duration, the nature of the fluid, and its quantity; the mechanical and microscopical examination of the two fluids and the two deposits, one proceeding from thoracentesis, the other from expectoration; and the symptoms and complications. After this, the various hypotheses which have been adopted to explain this accident may well be considered.

The expectoration of albuminous fluid after thoracentesis, according to M. Terrillon, presents three different characters, according to the quantity expectorated, and the gravity or mildness of the symptoms. The mild form is characterized by slight dyspnoea, and by the expectoration of a fluid in which the presence of albumen is revealed by nitric acid, and which varies in quantity from a few up to 700 or 800 grammes, when it has attained a sufficient duration, which may vary in time from a few hours to about a day. The intense form bears the following characteristics: acute dyspnoea; abundant expectoration (1200, 1500, 2000 grammes, and even more); frequent cough, generally spasmodic, accompanied by fine subcrepitant râles. The duration of these symptoms varies from several hours to a whole day. In the third and most serious form, the patient, after twenty or five-and-twenty minutes of comparative quiet, is suddenly seized with acute, very intense, and most painful dyspnoea, with spasmodic cough, accompanied by a frequent spitting of froth, after which death supervenes, with all the symptoms of asphyxia caused by the accumulation of liquids and spumous matter throughout the respiratory system. M. Terrillon relates only two fatal cases out of the twenty-one which he has been able to bring together, to which MM. Béhier and Liouville have added the record of a third. The escape of this albuminous liquid generally takes place from ten

minutes to one hour after thoracentesis. It is of a yellowish color, more or less transparent, according to the amount of expectoration; a persistent froth forms the upper layer, the middle layer being represented by the fluid, and the lower layer by a deposit of mucous products given off by the bronchi. It coagulates when treated with nitric acid.

The analysis made by M. Bergeret includes the daily examination of the two fluids, and the microscopic examination of the deposits of both. The pleural fluid evacuated by operation was, after filtration, amber-colored, alkaline, and poor in mucine. A hundred grammes, treated by an alcoholic solution of carbolic and acetic acids (Méhu's reagent), gave 1.61 grammes of albumen after drying. The expectorated fluid, mixed with mucus, was, after filtration, clear, slightly tinged with red, viscous, alkaline; and, when treated with acetic acid, gave a copious precipitate of mucine; 100 grammes, precipitated by Méhu's reagent, gave 1.42 grammes of dried albumen mixed with mucine. The microscopic examination of the deposit of the expectorated liquid showed epithelial cells in large quantity, together with pus-corpuscles and sometimes red blood-corpuscles. In the deposit of the liquid of thoracentesis, pus-corpuscles only, and very few red corpuscles, were seen.

The question arises, what are the possible relations between albuminous expectoration and the copiousness of the effusion? The cases reported by M. Terrillon show, in the first instance, the abundance of the liquid in the pleural cavity, of which the average was generally from two to two and a half quarts. The most minute care was always observed in the operations. As to the more or less grave complications which may have preceded the operation, it is easy to agree with M. Terrillon, that they could not possibly have had any direct influence on the accident under consideration. The syncopal condition, the cough, the striking of the lung against the canula, the passage of air through the canula, have all been given as predisposing causes; but very reasonable explanations have been opposed to such interpretations of the phenomena. The influence of the nature and age of the effusion on the production of the expectoration has been decisively proved to be *nil*, since the majority of the cases (15 out of 20) were instances of acute pleurisy, in which thoracentesis was performed twenty or thirty days after the commencement of the disease. Nor can heart-disease be really considered as a predisposing cause; since it either did not exist or was not detected in the cases of pleurisy. One circumstance remains to which some importance might be attached: the rapidity with which the pleural liquid made its escape was noticeable in all the cases cited by M. Terrillon. We shall return to this point. The expectoration can certainly not be confounded with bronchorrhœa: its difference of character is quite clear, as shown by the reaction given by adding nitric acid.

We now arrive at the hypothesis by which this expectoration has been explained. *Auctores certant*; and we find ourselves in presence of four opinions, arranged by M. Terrillon in the following order: 1. Perforation by the trocar; 2. Spontaneous perforation; 3. Re-absorption of the liquid remaining after thoracentesis; 4. Transudation of the sero-albuminous liquid through the alveolar walls, in consequence of rapid pulmonary congestion.

M. Féréol attributes the albuminous expectoration to the passage of the pleural liquid by the lung. In order to explain the spontaneous perforation, he imagines a special change, characterized by destruction of the epithelium and the connective tissue of the pleura, a sort of membrane being thus formed, which would allow the filtration of the pleural liquid into the lung, and its ex-

pulsion by the bronchi, without allowing the air to pass. This theory has caused one of the first who denied spontaneous perforation, M. Dujardin-Beaumetz, to remark, "Then let us employ powerful suction, such as that of the aspiratory apparatus." It is as difficult to demonstrate the existence of this perforation without pneumothorax, as it is rare to meet with pleuro-bronchial perforation in the adult. All observers have seen and cited instances of spontaneous pulmonary perforation, without pneumothorax, in purulent pleurisy; but not at all, or very rarely, in serous pleurisy. M. Barthez has demonstrated that in children absence of pneumothorax is the rule.

M. Féréol says that, there having been a preparatory process, ulcerative or otherwise, a fit of coughing comes on, and perforation occurs in the struggle. M. Moutard-Martin asks how this perforation is accomplished; and M. Féréol's answer is, "By a violent effort directed from the bronchial tubes towards the pleura; by a forced distention of the lung, which is no longer supported by a sufficient compression of the effusion; the air then contained in the bronchial tubes would be driven towards the pleura." This perforation, however, should take place at the moment when the vacuum is produced; but albuminous expectoration shows itself at a more or less distant period after the operation. We might further cite, against spontaneous perforation, Boule's case from Béhier's lecture (*Union Médicale*, 175), where the patient underwent four successive thoracenteses, each followed by albuminous expectoration. It is in fact not possible to admit that four spontaneous perforations should have occurred in one subject, or that they should have been found in both lungs, the operation having been performed on both sides. We must therefore give up M. Féréol's very ingenious hypothesis, and the subtle explanations with which he supplements it.—*British Medical Journal*, Oct. 4.

GLEANINGS FROM OUR EXCHANGES.

ANTIPYRETIC TREATMENT IN THE FEBRILE DISEASES OF CHILDREN.—Dr. G. Mayer has treated (*Jahrb. für Kinderheilkunde*, vi. 3, p. 271, 1873) typhus (enteric?) fever, pneumonia, scarlet fever, and erysipelas, occurring in children, by cold baths.

Of enteric fever (?) he treated more than twenty cases; all with a good result. The youngest child so treated was seven months old. The temperature of the water employed was 90° Fahrenheit to begin with, gradually reduced to 80° or even 70°. The duration of the bath was ten to fourteen minutes. An axillary temperature of 103.5°, or a rectum temperature of 103°, was regarded as the indication for a bath.

In catarrhal pneumonia Mayer abstains from baths; the danger to life lying, as he truly says, not in the pyrexia, but in the suffocation. In lobar pneumonia (croupal pneumonia, peripneumonia), on the contrary, antipyretic treatment is very useful. An infant, seventeen months old, was treated in this manner; in eleven days sixty baths, reduced to a temperature of 80° and 75°, were given. Mayer especially recommends cold baths or ice to the head in cases of pneumonia complicated with a convulsive tendency; deeming the convulsions to depend upon the pyrexia.

The results of cold baths in scarlet fever are not so satisfactory, except in the ataxic (or "malignant") form of the disease, which has been treated in this manner, as everybody knows, since the days of Currie (1805).

Quinine he has tried in enteric fever; for a child of six, from seven to twelve grains, in two doses, half an

hour or an hour apart, in the evening. A notable fall of temperature follows. Occasionally vomiting, deafness, and slight increase of diarrhoea ensue.—*London Medical Record*.

INOCULABILITY OF ECTHYMA.—Vidal, one of the physicians to the St. Louis Hospital, Paris, in an interesting paper in the *Annales de Dermatologie et de Syphiligraphie*, No. 5, 1873, gives the result of some experiments with the inoculation of the matter taken from the pustules of ecthyma. Two series of experiments are recorded, one with the pus of ecthymatous pustules developed in the course of grave typhoid fever, the other with the pus of ecthyma simplex. The experiments were conducted with every requisite precaution, and their results may be summed up as follows:

1. The pustules of the ecthyma of typhoid fever and those of ecthyma simplex are auto-inoculable.
2. The pustule of inoculation follows, in the phases of its development, a course identical with that of the original pustule. The first day, several hours after the inoculation, we see at the place of puncture a red point, already a little indurated, and which is usually the seat of considerable itching. The second day the redness extends itself, and an elevated, firm nucleus forms. The third day the redness is greater, the inflammatory indurated nucleus points and forms the base of a little vesicle containing a small quantity of cloudy, serous matter. The fourth day the pustule of ecthyma is perfectly characteristic, fully developed, and furnishes an inoculable pus. It desiccates by the ninth or tenth day, and the crusts fall from the sixteenth to the twentieth day.
3. The liquid taken from the second generation of the pustules is also auto-inoculable.
4. Its activity diminishes in the successive inoculations: the power to reproduce ceases with the third or fourth generation.

ABORTIVE TREATMENT OF BOILS.—The following, applied to boils with a camel-hair pencil or feather, gives great relief in a very short time. The inflamed surface, and a little beyond all around, should be painted with the medicine every fifteen minutes, or as fast as it dries, till a good thick coating covers the part. The throbbing tensive pain and the intense tenderness will be promptly relieved; the redness will subside; the smooth, shining integument will shrink and become wrinkled, and comfort will succeed torment. If the boil is in the first stage, it will disappear without slough. If slough has already formed, it will be quickly separated, and the cure soon complete:

R Tinct. arnicæ, ʒj;
Acidi tannici, ʒss;
Acaciæ pulv., ʒss. M.

It should be used as soon as prepared.—*C. B. Hall, in Cincinnati Lancet and Observer*.

COD-LIVER OIL MIXTURE.—A preparation that has met with much favor, under the above name, has been made by the writer from a formula given him by Mr. Hassard of Philadelphia. It is made as follows: R Fresh eggs, No. iv; lemon-juice, q. s. Place the eggs in a suitable vessel, and pour over them sufficient lemon-juice to cover them, and let the whole remain for twenty-four or forty-eight hours. Then pass the whole through a strainer, and add, with agitation, the following, and in the order given: To the lemon-juice and eggs add an equal volume of honey, cod-liver oil, and brandy or whisky. The whole forms a permanent emulsion, and will keep good during the summer months for a month, and longer in cooler weather. The taste of the oil can be completely covered by the addition of a few drops of oil of wintergreen or oil of bitter

almonds. This mixture is pleasant to take, and a valuable therapeutic agent.

P.S. Glycerin may be substituted for the honey.—*E. S. W.—Cincinnati Lancet and Observer*, Sept. 1873.

PERFORATING ULCER OF THE FOOT.—MM. Duplay and Morat (*Arch. Gén. de Méd.*, March and May, 1873) ascribe perforating ulcer of the foot to a degeneration of the nerves of the part. This degeneration may be of entirely peripheral origin, just as frost-bite induces degeneration of the nerves and a tendency to ulceration; or it may be connected with a more deeply-seated affection of the sciatic nerve, or with disease in the spinal cord. The authors, therefore, place perforating ulcer of the foot in the same category with the ulceration of the cornea which follows section of the trigeminus nerve. The principal symptoms agree with this view, being indicative of disturbance of sensation and nutrition. The inflammation which surrounds the ulceration affects all the tissues, including the arteries, which are sometimes diseased to so great an extent that many have attributed the ulceration to arterial sclerosis. The prognosis will evidently depend on the possibility of treating the nervous disorder with success.

INOCULABILITY OF EPITHELIOMA (*British Medical Journal*, September 20, 1873).—Dr. J. Wickham Legg reports the results of some experiments made upon guinea-pigs and white rats. In the cases of successful inoculation which have been recorded of late years, some hours have usually elapsed between the removal of the epitheliomatous growth from the human patient and its inoculation, thus making it probable that it acted as any other dead mass. In Dr. Legg's experiments the animals were prepared in advance, and not more than sixty or eighty seconds passed between the separation of the tumor and the inoculation of a thin slice taken from its most rapidly growing portion. This was done in five cases; the animals were kept alive for six months and then killed, but there were no discoverable lesions, new growths, or tuberculosis.

CHIONANTHUS VIRGINICA (*New York Medical Review*, September, 1873).—Dr. I. J. M. Soss recommends chionanthus as a potent alternative and cholagogue, and has found it of great value in hypertrophy of the spleen and liver in cases of extreme and persistent jaundice and indigestion. He uses a tincture made from the bark of the root in the proportion of eight ounces to a pint of alcohol.

MISCELLANY.

THE DANGER FROM LIGHTNING.—The Hartford *Courant* has been figuring up the chances of being struck by lightning, and arrives at the following reassuring results: "Taking the figures of the last census report for our facts, we find that during the year 1870 there were, in the whole country, 202 deaths from lightning-stroke. Let womankind take notice that out of these 148 deaths were of males, and only 54 of females. The total number of deaths from all causes was nearly 500,000. There were 2437 deaths from other causes to one death from lightning; and there were 190,883 persons living to every one killed by this cause. It is somewhat singular that the lightning was decidedly more destructive with both males and females between the ages of ten and thirty years than with any others;

between ten and fifteen years is, the most fatal time, but even then the number is very small. Much comfort for those still inclined to be timorous is to be found in going back further on the record. The deaths by lightning in 1870 were only eleven more than in 1860, while the population had increased more than 7,000,000, and the rate is declining, in spite of the hasty conclusions formed by reading the news of a day. In 1860 there were forty-eight deaths by lightning out of every 100,000 deaths from all causes; in 1870 the rate was only forty-two. But now, while only 202 persons died from lightning-stroke in 1870, there were 397 deaths from sunstroke, or nearly twice as many. Yet the number of persons who shudder when they see the sun rise would bear a very small ratio to those who shudder at the rising of the thunder-cloud. The rate of deaths by sunstroke has declined during the decade from ninety-one to eighty-one in 100,000 deaths from all causes, and, with the increase in care and information on the subject, is likely to decrease still more, but it will always probably be largely in excess of the lightning rate. It is also noticeable that there were 1345 deaths by suicide, while there were only 202 deaths by lightning: in other words, an individual is six times as likely to kill himself as lightning is to kill him."

MANUFACTURE OF CARMINE.—This is one of Nature's most gorgeous products in the way of color. That lovely, rich shade of red is solely produced from a decoction of the cochineal-bug. Wherever the cactus is indigenous, there this little insect is to be found in myriads, feeding on the plant and imbuing its own blood with the glorious red of the flower. Only the females are used for making carmine; but, as there are three hundred females to one male, there is not much difficulty in picking out that solitary representative of the ruling sex. Woman's rights have full sway in this particular branch of the insect kingdom. The excellence and purity of this color and vermilions—in fact, of all colors—depend upon careful and thorough washing in water. Some vermilions are washed as often as sixteen times before the pigment is sent to the drying-rooms. In the manufacture of some of the finer colors, too, milk, eggs, or cheese are used with the chemicals as purifiers. The most surprising thing, says a correspondent of the *New York Times*, describing the Plymouth Color Works at Bergen Point, New Jersey, is to see the water that is drawn off from the huge tanks of color after it has been well stirred and washed. The tanks being lined with fine muslin, not a particle of color escapes, and the water is pure and clear as drinking-water. Lakes of different shades are made from carmine combined with a chemical body, which cheapens the color and makes it of any desired hue.—*The Monthly Mirror*.

THE MALADY OF THE FIRST NAPOLEON.—The following interesting letter, along with a lock of hair, has been recently discovered by Major Young, of Lincluden, Scotland. It was written to his father by Dr. Short, principal medical officer at St. Helena at the time of

Napoleon's death: "St. Helena, 7th May, 1821.—You will, no doubt, be much surprised to hear of Bonaparte's death, who expired on the 5th of May, after an illness of some standing. His disease was cancer in the stomach, that must have lasted some years, and been in a state of ulceration some months. I was in consultation and attendance several days, but he would not see strangers. I was officially introduced the moment he died. His face in death was the most beautiful I ever beheld, exhibiting softness and every good expression in the highest degree, and really seemed formed to conquer. The following day I superintended the dissection of his body (at this time his countenance was much altered), which was done at his own request, to ascertain the exact seat of the disease (which he imagined to be where it was afterwards discovered to be), with the view of benefiting his son, who might inherit it. During the whole of his illness he never complained, and kept his character to the last. The disease being hereditary, his father having died of it, and his sister, the Princess Borghese, being supposed to have it, proves to the world that climate and mode of life had no hand in it; and, contrary to the assertions of Messrs. O'Meara and Stobo, his liver was perfectly sound; and had he been on the throne of France, instead of an inhabitant of St. Helena, he would equally have suffered, as no earthly power could cure the disease when formed."—*British Medical Journal*.

GARMENTS MADE WATERPROOF.—A writer in an English paper says, "By the way, speaking of water-proofs, I think I can give travellers a valuable hint or two. For many years I have worn india-rubber water-proofs, but will buy no more, for I have learned that good Scotch tweed can be made entirely impervious to rain; and, moreover, I have learned how to make it so; and, for the benefit of your readers, I will give the recipe: In a bucket of water put half a pound of sugar of lead and half a pound of powdered alum; stir this at intervals, until it becomes clear; pour it off into another bucket, and put the garment therein, and let it be in for twenty-four hours, and then hang it up to dry, without wringing it. Two of my party, a lady and gentleman, have worn garments thus treated in the wildest storms of wind and rain, without getting wet. The rain hangs upon the cloth in globules. In short, they are really waterproof. The gentleman, a fortnight ago, walked nine miles in a storm of rain and wind such as you seldom see in the South; and when he slipped off his overcoat his underwear was as dry as when he put them on."—*The Monthly Mirror*.

EIGHTEEN Norwegians, separated in September, 1872, from their ship on the northern shores of Spitzbergen, were forced to winter at a place on the shore called Mitterbuk, where they were all found, a few weeks ago, dead, by Captain Mack, who was sent in quest of them. They had no lack of food, of a kind, as biscuit was found beside them; but they wanted vegetables, and, scurvy setting in, they languidly crowded over the fire, and so died one by one. Want of provisions might

have proved their salvation; for men cast ashore at Spitzbergen immediately set about scraping antiscorbutics from under the snow, and keep up the circulation in hunting wild animals, whose warm blood when drunk also prevents scurvy, and whose furs supply clothing. Six Dutchmen, a good many years ago, wintered at Spitzbergen in this way, and survived. They were wiser in their generation, however, than the unfortunate Norwegians, who perished (as did also a second crew from Holland, who wintered there before them) by neglecting the pursuit of wild beasts and antiscorbutics, and shivering before the fire in their hut.—*The Canada Medical Times*.

M. B. A. OF FRANCE.—The *Medical Benevolent Association of France* held its fourteenth annual meeting April 20 and 21. Its finances are highly prosperous, the society having funded 335,046 francs. The proposition was made by the treasurer to begin granting annuities in 1874, that is, four years sooner than originally intended.—*Western Lancet*.

FEMALE DENTISTS.—In a short time, says the *Vienna Medical Press*, Fräulein Föckling, D.D.S., a young lady of Berlin nativity, will establish herself in Berlin in the practice of her profession. Miss Föckling graduated in Baltimore, March 1, and remains at present in the office of a celebrated dentist of that city, to perfect herself in practical dentistry. The *Allg. Mediz. Centralblatt*, which communicates this interesting intelligence, reports further that the young lady prosecuted her studies with the greatest zeal and with remarkable success. As she ascended the platform, March 1, attired in a most elegant robe *en train*, and received her diploma from the Dean of the College, she was overwhelmed with applause and bouquets of flowers.

PROFESSOR ROKITANSKY.—This distinguished ornament of the Vienna Medical School has announced to the Professoren-Collegium that next year he will have attained his seventieth year. According to the regulations, he should then retire from his professorship and be placed on the pension-list. It seems, however, that, seeing the great loss his retiring would inflict upon the Vienna School, of which he may almost be considered the founder, an effort will be made to have his case regarded as an exceptional one, as long as his present good health and teaching power continue.—*Boston Medical and Surgical Journal*.

UNFORTUNATE CASE OF SNEEZING.—In a letter Dr. Y. A. Winn says, "I will mention a very singular case, —singular to me at least. A gentleman informs me that when prompted to sexual commerce he is seized, immediately prior to the act, with a fit of violent sneezing: not unfrequently even the *thought* of coition produces this effect. The gentleman being married, we are at a loss for a satisfactory remedy. Fortunately, his wife has never *apparently* noticed this peculiarity. If she should, and he did much sneezing in the presence of other ladies, even *sneezing* might be a sufficient ground for divorce."—*Western Lancet*.

NATURAL RED SILK.—M. Ruimet des Taillis, writing in the *Chronique de la Société d'Acclimatation*, states that by feeding silkworms on vine-leaves he has obtained cocoons of a magnificent red, and, by employing lettuce, others of a deep emerald-green. M. Delidon de Saint-Gilles, of Vendée, has obtained silk of a beautiful yellow, other samples of a fine green, and others again of a violet, by feeding the silkworms on lettuce or on white nettle. He points out that the silkworms must be fed on mulberry-leaves when young, and supplied with the vine-, lettuce-, or nettle-leaves during the last twenty days of the larva-stage of their life.—*Druggists' Circular*.

EVERY physician in regular practice, in city and country, should not only take one or more medical journals, but contribute as well. A large and lucrative practice, a high and influential position, are not alone sufficient to perpetuate a worthy name and reputation. These are perishable and will die out, when well-timed and well-recorded facts will last and establish true and genuine worth. Zimmermann remarked "*that the greatest medical writers of any age were the best physicians.*" Those who communicate their views should rather be encouraged than decried.—*President's Address, Canada Medical Association*.

CHEERFUL.—In the province of Quebec, lunatics are generally sent to jail and kept there till they become permanently insane and hopeless, when they are sent to the asylum to become permanent burdens on the province.—*The Canada Medical Record*.

BURNING OF THE DEAD.—A society has recently been formed at Zurich, Switzerland, the members of which pledge themselves to have their bodies burned after death, in place of the usual burial. The society already has a large number of adherents.

PRURITUS VULVÆ.—Take of bichloride of mercury, one part; alum, twenty parts; starch, one hundred parts; water, twenty-five hundred parts. Mix. Apply freely to the part.—*Revue de Thérap.*

THE brain is a splendid piece of tapestry, of which the Creator has furnished the canvas and we have filled in the stitches.—*Fournier*.

THE locusts have done so much damage in Nepaul, India, during the past season, that a famine is imminent.

NUMEROUS cases of enteric fever have occurred in the Rhymney valley, South Wales.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 14, 1873, TO OCTOBER 20, 1873, INCLUSIVE.

GHISELIN, J. T., SURGEON.—Relieved from duty in Department of the Columbia, and ordered to Department of Texas. S. O. 206, A. G. O., October 15, 1873.

HUBBARD, VAN BUREN, ASSISTANT-SURGEON.—Granted leave of absence for thirty days. S. O. 162, Department of the Gulf, October 11, 1873.

KIMBALL, J. P., ASSISTANT-SURGEON.—Granted leave of absence for thirty days. S. O. 224, Department of Dakota, October 9, 1873.

SATURDAY, NOVEMBER 1, 1873.

ORIGINAL COMMUNICATIONS.

CASE OF ECLAMPSIA IN A NEW-BORN INFANT.

BY ELLWOOD WILSON, M.D.

THE following case is of some interest as illustrating one of the rarer unavoidable evils following the use of the forceps in prolonged and difficult labors.

Second pregnancy; head-presentation, fourth position (vertex to right sacro-iliac symphysis). Ether administered to modify the intensity of the pains, but not beyond slight muscular relaxation. The forceps were applied *without difficulty* to the sides of the child's head, and traction made with each returning pain during a period of three hours, until delivery was effected, the grasp of the instrument being relaxed during the intervals between the pains. The labor was rendered difficult by narrowing of the pelvic outlet; its whole duration was thirty-two hours. The child, a male, and of large size, seemed feeble when born, but reacted pretty well. It was greased and wiped, washing being interdicted, and simply wrapped in a blanket, kept upon its right side, ten drops of brandy being given every two hours in milk and water, equal parts. The head was moulded by pressure, and slightly marked by the blades of the forceps. Twenty-four hours after birth it seemed stronger, and permission was given the nurse to wash and dress it. Some exhaustion followed, and in a short time two convulsions occurred in quick succession, and, after an interval of nearly an hour, a third during my visit. The muscles of the respiratory tract were chiefly affected. The child suddenly ceased breathing; its surface became livid, its extremities cold. At first the heart's action was not altered, but during the continuance of the fit the pulse gradually failed, until at length it was scarcely perceptible. The thumbs were drawn slightly inward; there was no general muscular rigidity, no twitching of the face or extremities; the muscles of the eyes were not affected. This convulsion lasted two minutes, and terminated with a long, deep inspiration, followed by a fit of crying, immediately upon the introduction of a small conical lump of ice into the rectum. Convulsions recurred at intervals of from fifteen to forty minutes during fifteen hours, but the use of the ice, whether at once at the beginning of the seizure or after waiting until it had lasted some moments, was invariably followed almost immediately by the long inspiration and fit of crying,—the relief of the paroxysm. Every effort at deglutition caused a return: the treatment was therefore administered by enema. It consisted of five grains of bromide of potassium every two hours, alternating with fifteen drops of brandy in milk. The child was kept strictly upon its right side, and surrounded with artificial warmth. The attacks gradually decreased both in intensity and frequency, and finally ceased. Stimulus and small doses of the bromide were continued for several days. More than three months have since elapsed without the recurrence of a symptom referable to the nervous system. The child is well nourished, and apparently in perfect health. The contraction of the outlet of the pelvis in the mother of this child is very marked. Her first child was born after a difficult labor of thirty-six hours, but so enfeebled that it died in a short time.

I have given the history of this case at some length,

in order to point out what I believe to be the cause of the convulsions: that is, the prolonged pressure of the ends of the forceps-blades at the base of the cranium, producing some slight derangement of relations of the structures of the brain at its base, and consequent *tendency* to convulsions. This tendency—not strong enough to overthrow the equilibrium of the nervous system as long as the child's general strength did not fall below a certain condition—developed into convulsions as soon as it was reduced by the insignificant shock of the bath and exhaustion of dressing, to which children, as a rule, may be exposed with impunity on the second day.

Mere moulding of the head by pressure of the bony walls of the pelvic canal—a pressure exerted upon the cranium at its greater diameters, and not upon the base—has not, in my experience, given rise to convulsions. W. J. Little, however (see Transactions of the London Obstetrical Society, vol. iii. p. 293), remarks that convulsions are very apt to occur immediately upon or at varying periods after difficult births, and attributes this symptom of disorder of the nervous system in the great majority of cases to the congestions resulting from partial asphyxia, rather than to mechanical injury of the nervous structures. But he quotes North as saying, "It cannot be doubted that convulsions occasionally arise from excessive and long-continued pressure of the head during protracted labor." Cazeaux fails to enumerate convulsions among the accidents following the use of the forceps. Spastic rigidity is apt to occur subsequently.

The forceps used were the short forceps of Davis, and there was no difficulty in locking the blades; although there is no doubt that the change in the shape in the head through long compression, increasing the occipito-mental diameter, interfered with the coincidence of the curvature of the forceps with that of the head, and in so doing brought the ends of the blades to press more directly upon the cranial base. Graily Hewitt in 1861 called attention to the fact that this change in the shape of the head renders the application of the forceps difficult, and suggested in such cases the use of a longer blade with a less decided curve.

Ether, which always when freely used and long continued enfeebles the child, and the unguarded use of which is without doubt in the present era of obstetrics the cause of multitudes of still-births, does not cause convulsions.

The treatment of the paroxysm by ice to the anal region, or by small pieces of ice introduced into the bowel, was attended by the most marked results. More than once the convulsion, unusually prolonged, seemed to be passing into coma, when the ice quickly brought it to an end.

Certainly in this case the feebleness of the child, and the fact that it was but a day old, forbade the use of most of the means recommended for the relief of the convulsive paroxysm, while the severe type of the convulsions and the imminent danger of death precluded the use of others less speedy in their action. By the application of ice to a part so largely supplied with nerves, a sudden powerful

impression was produced upon the spinal system, and that by a remedy at once near at hand, entirely controllable, and incapable of producing depressing or traumatic secondary effects.

DILATATION OF THE FEMALE URETHRA.

BY OSCAR H. ALLIS, M.D.,

One of the Surgeons to the Presbyterian Hospital.

I REPORT the following cases, not that they present any new feature, but rather as confirmatory of cases previously favorably commented upon by other writers.

Case I.—Mrs. —, 58 years of age; vesical calculus; had often passed concretions during micturition, and some of large size. I visited the patient every day or every second day for about two weeks, and at each visit effected a greater dilatation of the urethra. As soon as I could introduce the forefinger, Dr. Turnbull, who had placed the case in my hands, and Dr. Curtin, assisted me in completing the dilatation and the extraction. There proved to be two large calculi, and the circumference of the larger, when grasped with the ordinary lithotomy forceps, was three inches and a half. At the suggestion of Dr. Turnbull, the bladder was injected with cold water, to check any bleeding that might ensue had the walls of the bladder been injured, and, to the surprise of all present, not a drop was permitted to pass the already contracted sphincter. The patient made a rapid recovery, without suffering a moment's incontinence of urine.

Case II.—Mrs. —, æt. 53; married; the mother of three children. In the spring of 1872 she began to complain of pain in the hypogastrium. The pain was neuralgic in character, not constant, and aggravated under certain changes of the weather.

The slightest distention of the bladder gave her pain, and the sudden stoppage of the urine during micturition led to the suspicion that calculus might be present. Still, the explorations of the bladder with the sound, and examination of the urine, gave no satisfactory clue to the malady. Baffled in every attempt to give relief, Dr. Groom, of Bristol, in whose care the patient was, requested me to dilate the urethra and make a digital examination. This was effected in about fifteen minutes under ether, and a polypus was found at the base of the bladder, attached to a roughened thickened portion of the bladder at a point corresponding to the right side of the pubes. The diagnosis was thus established, the difficulty removed, and with the happiest results, and, what especially concerns us now, no incontinence of urine.

The mode of dilatation will be noticed in each case. In the first it was prolonged and vexatious to both patient and physician. In the second it was rapid; yet in the first the dilatation may as justly be called *rapid*,* for when I went to the patient the urethra would only admit the finger, and in about fifteen minutes it had been dilated to a circumference of three inches and a half.

I can see nothing to favor gradual dilatation, whether the object be to explore the bladder with the finger or to extract foreign bodies from it. The female urethra is under all circumstances very dilatable. There are many well-authenticated cases of

large calculi having escaped with the urine from the bladder, and a case is reported of obstructed vagina in which coitus took place habitually through the urethra.

During the latter stages of dilatation the progress must be gradual, for the limit of distensibility is being reached, beyond which rupture of the fibres must take place.

The instrument used—and a most admirable one for the purpose—is depicted in Gross's Surgery, under "Dilatation of the Female Urethra."

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS, M.D.

Reported by J. B. ROBERTS.

REDUCTION OF AN AXILLARY DISLOCATION OF THE HUMERUS OCCURRING DURING PUERPERAL CONVULSIONS.

MRS. D., aged 20, was seized during parturition with puerperal eclampsia, in which the convulsions were so violent that she sustained from muscular contraction an axillary dislocation of the right humerus.

The great variety of motion allowed the arm necessitates a peculiar mechanism of the shoulder-joint, which renders it especially subject to dislocations; and we accordingly find that of all luxations in the body that of the head of the humerus is the most frequent.

The head of the bone may be thrown into the axilla, upon the ribs below the clavicle, or backwards upon the dorsum of the scapula, constituting respectively the axillary, thoracic, and sub-spinous forms of the dislocation. The thoracic and sub-spinous varieties are very rarely seen, but that into the axilla is of frequent occurrence, generally, however, being produced by direct violence, and but seldom by muscular contraction. The injury as a result of puerperal convulsions is very uncommon, though instances of dislocation by muscular contraction during epileptic seizures are met with not unfrequently.

In the patient the contour of the shoulder is decidedly changed by a marked flattening where the roundness of the deltoid should be, and an unnatural prominence of the acromion, under which there is a hollow, caused by the removal of the head of the bone from its normal position. The distance from the top of the shoulder to the axilla is materially increased, differing from the uninjured side by at least an inch; the arm is lengthened; upon rotation of the limb the head of the humerus can be distinctly felt in the axillary space; and the elbow is thrown out from the body by the tension of the deltoid muscle.

It has been stated by some surgeons that in axillary dislocation of the humerus the patient cannot bring the elbow in front of the body, so as to grasp the opposite shoulder with the hand; but although this is true in this instance, it was not in the case brought to the clinic two weeks ago, where the patient could place her right hand on the left shoulder without any difficulty whatsoever.

In injuries about the shoulder-joint a careful examination is always imperatively demanded; for, though the symptoms of dislocation are generally characteristic, yet there are obscure cases which the surgeon may fail to recognize, unless the investigation be thorough and complete.

* I use the term *rapid* as implying that the dilatation has all been accomplished at a single visit, and not with reference to the number of minutes necessary to accomplish it.

When the dislocation is of recent date, reduction can be readily effected; but when left until a considerable period of time has elapsed, the operation is generally unsuccessful, and frequently attended with great danger to the important vascular and nervous structures in the axilla.

As the luxation in this instance occurred only three weeks ago, I shall endeavor to reduce it by using my heel as a fulcrum in the armpit and making extension on the forearm with both hands. The patient is thoroughly anæsthetized, in order to relax the muscular system, and then, having put a folded towel in the axilla, I place my heel, divested of the boot, against the luxated bone, making at the same time strong extension at the wrist, and by this means cause the head of the bone to slip into the glenoid cavity with a snap.

If this had been an old dislocation, it could not have been reduced by this simple manœuvre, but would have required the application of a much greater amount of force, which even then might have proved ineffectual, or have been followed by such disastrous consequences as rupture of the axillary artery or vein.

The period after which the surgeon should refrain from undertaking reduction cannot be fixed absolutely. It depends upon the amount of plastic inflammation that has occurred, and upon the degree of motion of the joint, which, if considerable, may be assumed as evidence that a false socket has been formed, and that attempts at reduction will be useless.

After reduction it is important to keep the arm supported in a sling, and to prohibit extensive motion in any direction, lest there be a recurrence of the displacement. The subsequent inflammation must be combated upon general principles, and the occurrence of ankylosis prevented by passive motion.

STRICTURE OF THE ŒSOPHAGUS FROM SWALLOWING LYE.

Mary H., aged 2 years, drank about three months ago some of the "concentrated lye" of the shops, which by the resulting inflammation has produced organic stricture of the œsophagus.

The powerful alkali, having corroded the mucous membrane of the lips, tongue, and throat, set up an intense inflammation, during the progress of which the destroyed tissue came away in large patches, and the patient was unable to swallow any solid food. After the expiration of six weeks the inflammatory action subsided sufficiently to permit the deglutition of bread; but a short time subsequently this became again impossible, so that at present nothing but liquids can pass into the stomach; and even these are at times ejected by regurgitation.

One of the most frequent causes of organic strictures of the œsophagus is inflammation arising from the action of acids or alkalies that have been inadvertently swallowed, which even when not very concentrated are capable of producing a degree of inflammation sufficient to cause contraction of the calibre of the tube.

The most frequent position of the constriction is opposite the cricoid cartilage, for in that situation the œsophagus has normally the smallest diameter. Just above the stricture there is usually a dilatation of the tube, the result of pressure exerted by the food arrested in its downward course by the obstacle.

Here is a specimen, for which I am indebted to Dr. Barton, my chief assistant, taken from a child who died with a stricture of the gullet. The constriction is several inches long, and entirely impervious, so that the patient perished from inanition, as no food passed into the stomach for some time previous to death.

The only available treatment in stricture of the œsophagus is long-continued dilatation with the bougie; but in this case, since it is impossible to have the co-opera-

tion of the patient, it is not judicious to endeavor to carry out this plan. The administration of chloroform at every introduction of the instrument would be impracticable; and, unless completely anæsthetized, the child might by struggling cause the operator to rupture the already diseased tube. Palliative measures must therefore be adopted, and the patient's strength kept up by nutritious liquid food, for it is probable that the child does not obtain sufficient nourishment through the narrowed œsophagus to meet the requirements of the system.

ONYXITIS OF THE INDEX FINGER.

The left index finger of this girl has been sore for two months, being now indurated and enlarged and having a curious bulbous appearance. The trouble began with a small ulceration at the root of the nail, which, gradually increasing in extent, ran around the circumference of the nail, and entirely destroyed it. There is now no nail upon the finger, but in its place a foul, unhealthy-looking ulcer, which gives the girl, particularly during the night, a great deal of pain.

The patient thinks the disease was brought on by a slight injury which the finger sustained a short time previous to the appearance of the ulcer. This is quite probable, as onyxitis, or onychia maligna, as some designate the affection, has not unfrequently some external violence for its immediate exciting cause, though it is in reality a manifestation of constitutional taint, being almost invariably dependent on hereditary syphilis.

In treating onyxitis the bowels should be kept well opened, and mercury administered until the occurrence of slight ptyalism shows that the system has been brought under its influence. As it is often well to employ the iodide of potassium, sodium, or ammonium, in combination with the mercurial, this little girl shall take three times a day one grain and a half of the iodide of sodium, which is less nauseating than iodide of potassium, with one-twentieth of a grain of the corrosive chloride of mercury. In addition to this constitutional treatment, she shall use emollient poultices and sugar of lead locally.

Depletion of the parts by scarification or by means of Swedish leeches would no doubt be attended with very beneficial results; and it is possible that this may be resorted to hereafter in conjunction with the foregoing treatment.

ST. MARY'S HOSPITAL.

SERVICE OF JAMES CUMMISKEY, M.D.

Reported by JAMES A. MEARN, M.D.

ABSCESS OF THE LIVER.

ROLAND J., æt. 44, married man, proprietor of a liquor-house in this city, was admitted to the medical wards August 29. His condition on admission was as follows:

Patient was suffering from a high fever, frequent pulse, intense headache; very restless and irritable (had had a severe chill the day previous); complained of pain in right side on inspiration; breathing interrupted, tongue heavily coated, bowels costive; had slight hacking cough, but no expectoration. On inspection, the right side was bulging slightly. On percussion, dulness of base of right lung, and area of dulness of liver enlarged.

Diagnosis at this time was pleurisy. He was treated by blisters over seat of pain; a fever mixture was given; bowels opened by saline purgatives. In two weeks he was able to walk around the wards, and a few days afterwards went home for a day. He came back, and was apparently convalescent.

On the 21st of September he went down to service in

the chapel; the room was cold and damp; after going up-stairs he was seized with a chill, and had to go to bed. This time no symptoms indicating a return of the pleurisy were discovered, but each day the swelling in the right hypochondriac region increased. The liver became enormously enlarged. Dulness as high as upper margin of fourth rib, and extending three inches below margin of the ribs. The patient emaciated rapidly; had slight diarrhoea; appetite very bad; tongue became heavily coated; breath offensive; skin slightly jaundiced; pulse frequent, and scarcely perceptible. He was given blue mass ten grains daily, with nitromuriatic acid, diluted, fifteen drops every four hours, for five days. At this time he was given stimulants alone, and poultices applied over the swelling. This was continued for nine days. Fluctuation was perceptible. An exploring-needle was introduced, which contained pus on withdrawing it. The following morning the swelling had almost entirely disappeared. He was passing pus by the bowels. He became delirious, and died in twenty-eight hours.

Post-mortem examination revealed the following condition. A cavity occupying nearly the whole of the right lobe, ulceration through into the duodenum, and also into the peritoneal cavity. Over two quarts of pus were found in the liver and abdominal cavity. Adhesions had formed to the parietes opposite the fifth, sixth, and seventh ribs. The left lobe was somewhat enlarged and softened.

TRANSLATIONS.

ON THE OLEO-STEARATES, AND PARTICULARLY ON THE OLEO-STEARATE OF ZINC.

Translated from the *Bulletin Générale de Thérapie*, Sept. 1873,

BY ARTHUR VAN HARLINGEN, M.D.

WE desire to call the attention of practitioners to the advantages which these compounds present, both as entering into particular pharmaceutical preparations, and as to the therapeutic results which may be hoped for from their use.

Oleo-stearates (or rather oleo-stearo-margarates) are salts which have as bases oxides of the various metals, and as acids the oleic, stearic, and even margaric; and which are extracted from fatty substances by saponification.

Two processes may be employed for the preparation of these salts: one, which is direct, consists in mingling in presence of a certain quantity of water the different oxides which it is desired to combine, and the acids, or rather the natural fatty substances which are found in combination with glycerin under the names of oleine, stearine, and margarine. In this process the action of heat is often necessary, in order that the combination may be more easily effected.

This method is similar to that by which almond soap (oleate of soda), white soap, and lead plaster (oleo-stearo-margarate of lead) are prepared.

In other cases, and particularly where the oxide which is to enter into combination is very slightly alkaline, or of feeble solubility in water, and where, on the other hand, the oleo-stearate is insoluble in the same vehicle, it is necessary to have recourse to a second process, which permits of obtaining the salt indirectly and by double decomposition.

It is by this process that the oleo-stearates of iron, copper, mercury, etc., and of the various alkaloids, are obtained.

For this purpose a solution of almond soap is added in small portions to a solution of some soluble salt, with the base of which it is desired to obtain an oleo-stearate, until a precipitate is formed. Care must be taken always to employ an excess of the solution of soap, the presence of which excess is recognized by the milky tint of the supernatant fluid, the latter being clearly separated from the precipitated oleo-stearate.

That metallic salt should be chosen which precipitates most easily: thus, for iron or copper the sulphate, for mercury the per-nitrate, should be used; avoiding in the latter an excess of nitric acid, which possesses the property of decomposing the alkaline soap and setting free the fatty acids.

For the oleo-stearates of the alkaloids as proposed by M. Tripier, the chlorides of morphia, quinia, etc., are used.

The salts, as we have said, offer as pharmaceutical preparations several advantages, which have been pointed out by various writers, particularly M. Jeannel.

They allow, by their easy solubility in fatty substances, the preparation of ferruginous oils, and pomades containing active principles (oleo-stearates of morphia, quinia, etc.), where the state of solution in the excipient in which they exist makes them preferable to similar preparations where the active principles are incorporated by simply mixing or are dissolved in water, and are perhaps much less easy of absorption.

Finally, the oleo-stearates lend themselves successfully to various therapeutical applications. To give a single example, we may cite the oleo-stearate of zinc, which, mingled with a convenient quantity of an unctuous excipient, as in the following formula, gives excellent results in the treatment of chronic eczema accompanied by itching:

R Oleo-stearate of zinc (dry), 3 parts;
Mutton-suet, 15 parts;
Oil of sweet almonds, 15 parts.

Slowly incorporate the oleo-stearate of zinc with one part of the oil of almonds in a slightly warmed porcelain mortar, and add, little by little, the melted and partially cooled mixture of the remainder of the oil with the suet.

EPISTAXIS FROM A LEECH IN THE NOSE.—Dr. Amaducci was called to a boy aged 6 years, who had had obstinate epistaxis for a week, for which no cause could at first be assigned; the boy was healthy, and there was no family history of hemorrhagic diathesis. On being questioned, he said that the hemorrhage commenced some hours after he had drunk water from a brook. Cold water was injected into the right nostril, and the coagula were removed; a leech was then discovered adhering to the mucous membrane, and was removed by polypus-forceps. After this, the epistaxis ceased entirely. Dr. Amaducci believes that the leech was first taken into the mouth, and that it thence crawled into the nostril.—*Il Raccoglitore Medico*, No. 25, 1873; and *Allgemeine Medicin. Central-Zeitung*, Aug. 13.

TREATMENT OF ASTHMA.—Dr. Ad. d'Evot (*Rev. de Thérap.*) gives some directions as to the remedies to be used in asthma. Twelve grammes of flowers of sulphur, with one gramme of tartarized antimony, are mixed with honey and powdered gum and divided into sixty pills. Three of these represent the dose of Debreyne's powders, and one pill is given morning and evening.

Morning and evening a sheet of nitre paper may be burned in the bedroom or alcove of the patient. The paper may be prepared of white filter-paper, dipped in a solution of nitrate in the proportion of a drachm to an ounce.—*The Doctor*.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 1, 1873.

EDITORIAL.

ORAL SURGERY.

IN the *Dental Cosmos* for October is a very able editorial from the pen of Dr. James W. White, in answer to the question of the London *Lancet*, What is Oral Surgery? From it we extract the following, since it seems to us to contain as forcible an argument as can be made in favor of "Oral Surgery:—"

"An oral surgeon is one who, having received a general medical and surgical education, is drawn by interest or inclination to the special study and treatment of all abnormal conditions of the mouth, as are others to certain lines of practice now long enough established to have recognition as specialties. Just where such special practice shall begin, what it shall include, and where it will find its limitations, will depend, as in the practice of every other specialty, on the inclination and capabilities of the practitioner.

"If, as suggested by the London *Lancet*, it finds its boundary in 'stopping and extracting teeth,'—limited to a routine of mere mechanical manipulation,—the attempt to appropriate on such a basis of work or merit the honors of a learned profession is simply to court ridicule; while, on the other hand, to attempt to be an oral surgeon without the foundation of a medical education is neither more nor less than quackery. The *Lancet*, familiar apparently with only that class of dentists who are known among us as 'tooth-carpenters,' is astonished when a dentist aspires to do anything higher than 'to stop and to extract teeth.' Query: Is London dentistry not yet beyond the days of Paré? But, though unknown to the *Lancet*, there are in England, as well

as in this country, those in the dental profession not unknown to fame,—men who have earned, by study and practice, the title of oral surgeon; whose experience and proficiency in the treatment—medical, surgical, artistic, and mechanical—of all lesions of the oral cavity entitle them to a name indicative of special knowledge and skill equally with those to whom are freely accorded the titles of aural or ophthalmic surgeons.

"To deny recognition of the force which is developed by concentration is simply absurd. It then only remains to inquire if the lesions of the mouth are sufficiently serious and of such special character as to justify devotion to their study and treatment as a special branch of medical practice. No surgeon, we think, will deny that they are among the most serious and fatal of the lesions of the body, and that their treatment demands a degree of knowledge and skill which renders this department the most difficult in the range of a general surgical practice. A vast amount of suffering and disfigurement, and deaths not a few, are fairly chargeable to the malpractice, or want of practice, of those who, however learned or skilful in other directions, are incompetent to treat dental and associative lesions, because of having made no special study of the subject.

"That the majority of those now practising dentistry are worthy, in any wide sense, of the title of oral surgeons is not claimed. Too many, it may be, are quite satisfied 'to stop and to extract teeth;' but in the ranks of the profession are men whose ambition has a wider range, and who are acquiring a legitimate reputation in the medical profession as specialists.

"That the profession, now considered by the *Lancet* as devoted to a strictly mechanical pursuit, is to mean, in the near future, vastly more than this, we firmly believe. Let the young men now entering the ranks understand that the dentist is soon to be assigned his true position, either as a mechanic or a specialist in medicine. There cannot much longer be any middle ground. He is to blush when called doctor, or is to feel himself qualified to perform a doctor's duties."

In the address to the Canadian Medical Association, given at their late meeting by their president, the other side of this discussion is earnestly upheld; and the force and humor of the following extract are such that no apology is needed for its introduction here:

"Oral surgery carries the science from the top of the mouth above, past, and including, all the teeth, incisors, canines, bicusps, and molars; past the uvula, past the fauces and anterior palatine arch; past the right, ay, and the left tonsil; past the posterior palatine arch to the epiglottis, catching up in its way the apertures of the various salivary ducts, and there leaves it. But it cannot, in this age of unrest, stop there. There is room and capitals to furnish titles to the laryngeal, the tracheal, the clavicular, the sternal, the costal, the intercostal, the axillary surgeon, the humeral, the pa-

rietal, the genital, the inguinal, the femoral, the popliteal, the pedal, the phalangeal surgeon; but here, again, we encroach on the *terrain* of the comfort-giving corn-doctor, the chiropodist, to whom I would suggest the appropriation of the title of D.C.S., Doctor of Chiropedal Surgery! And why not? A toe is as good as a tooth, and there are fewer of them."

We believe specialism in medicine to be a necessary outgrowth of the extension of our science and art; but, of course, there is a possibility of carrying it too far,—of dividing up too finely,—of pulverizing into dust instead of breaking into large fragments fitting into one another and capable of being joined together into a united whole. The question then is, Is oral surgery sufficiently distinct and of sufficient magnitude to be worthy of rank as a specialty?

In considering this, it seems to us of vital importance that we recognize the true position of *dentistry* and of *dentists*.

Argue and reason as we will, laud dentistry to the skies, or degrade it to lowest rank, the fact remains, that the great bulk of the work to be done is purely mechanical; that whilst a few practitioners, like our friend Dr. Garretson, may climb from tooth-plugging and tooth-pulling to the performance of the most serious operations, involving life itself,—from being skilful dentists to being as skilful surgeons,—the great bulk of the profession must spend their lives in a monotonous round of purely mechanical labor, labor in which mechanical and artistic skill along with personal qualities are the sole guarantees of success.

The higher education, the wider culture of the physician, though it may contribute, is in no sense a necessity, to such success; and just so long as this is true, so long will a very large proportion of dentists neglect that culture which, whilst it may be an ornament, is not a necessity for the practice of their profession. Here, it seems to us, the matter rests. Dentists—we mean the general mass—have at present no claims to be recognized as representatives of a branch of our profession; many dentists are doctors, some of them are "oral surgeons," and as such we receive them into the brotherhood; but the great mass must probably always remain as they are at present,—*dentists*,—worthy citizens,—we do them no disrespect,—artists of ability, many of them,—but yet in no sense practitioners of medicine, in no sense entitled to recognition as such.

The professions of dentistry and of medicine conjoined in one person, but they are essentially distinct, and a man may assuredly be an

excellent dentist without being a doctor, or an excellent doctor without being a dentist.

In truth, we can see no necessity for "oral surgery" being a specialty. Is cancer of the jaw different from cancer of the rib, or any more different from cancer of the rib than the latter is from cancer of the vertebra or cancer of the tibia? Is every bone to have its specialist? In such a specialty as the eye, profound study of sciences and the use of instruments not employed by the general surgeon are necessary; but not so with "oral surgery."

Further, we see no reason for believing that a man can take out a jaw-bone or diagnose an epulis any better for knowing how to plug a difficult molar or to counterfeit with consummate skill a lost incisor.

Far better preparation for such work, it seems to us, is long-continued daily practice in resecting other than jaw bones, and in diagnosing tumors in other parts of the body than the face,—practice to be obtained only in the wards of the general hospital and the office of the general surgeon, not at all in the usual work of the dentist.

Finally, oral surgery has no natural boundaries,—no Rhine or Pyrenees which shall limit it. This very day, chancing to be at the clinic of the great apostle of oral surgery already alluded to, we saw present three cases, the first of which was an erectile tumor of the vertex, the second an occipital tumor, believed to communicate with the brain and to be arachnoidal. We can conceive of the oral surgeon crawling downwards to the anus; but how arachnoidal tumors and cephalic varices are connected with the mouth passes our comprehension.

We would like to see dental schools attached to our medical colleges, and opportunity afforded to our medical students to learn something of diseases of the teeth, or even, if they like, to become practical dentists. We believe that in many parts of our country the practice of dentistry would afford training in the use of the fingers, occupation and honorable support to young, unemployed, almost starving, surgeons, and, at the same time, open the paths to the higher fields of their life-work.

In very many of our country towns and villages even respectable dentistry is a lost art, or rather an art that has never been found. A very few months' instruction would enable any young physician of a mechanical turn of mind to extract teeth and to plug, under ordinary circumstances, with credit to himself. The work of two or three hours would give him at least a bare livelihood, and at the same time offer excellent opportunities for gaining the confidence of his neighbors.

This is no mere fancy sketch: we have known

the door to high success as a practitioner of medicine opened in this way.

ILLEGAL PRACTICE OF MEDICINE IN CONSTANTINOPLE.

A WRITER in a late number of the *Gazette Médicale d'Orient* calls attention to the prevalence of the illegal practice of medicine in Constantinople, and alludes to its legitimate effect as seen in a case which had lately created some stir in that city.

A young gentleman, feeling unwell one day, applied to a certain apothecary for relief. That worthy diagnosticated "worms," and put up a package of powders, which, he assured his victim, would kill the troublesome parasites.

The desired relief came, but in an unexpected form. After taking the first powder the patient fell into convulsions with tetanic spasms, and shortly died.

At the subsequent examination by the legal authorities it appeared that the apothecary had either given strychnia in mistake for santonin, or, what seemed more probable, had by some strange blunder made his powders from the receptacle containing strychnia, instead of from that in which white sugar was kept, the two "elbowing each other fraternally" on the shelf.

It would seem from the account of the writer above quoted that a stringent law relative to the qualifications of practitioners of medicine, and providing inspectors, etc., etc., does exist, but that, like some laws which might be mentioned nearer home, it is more ornamental to the statute-book than useful to the public.

ACCORDING to the London *Lancet*, at the recent meeting of the British Pharmaceutical Conference the subject of marking in some way prescriptions calling for unusual doses of medicine was discussed. A Mr. Hampson proposed that the initials of the prescriber be written in brackets immediately after the unusual dose, thus:

Tr. digitalis, $\frac{3}{4}$ ss [J. R. L.]

and asserted that this was always done in this country (United States)!! In Germany and Austria, it is stated, it is the custom to put an exclamation-mark. We think the adoption of some such custom with us would be very well, and would tend to aid apothecaries in detecting those mistakes in prescribing which every practitioner makes sometimes in his life.

IN another column will be found a letter from Prof. Gross, in regard to the Miller Memorial Home. Whilst endorsing the sentiments of the venerable professor to the fullest extent, we would like to add one word. The popular reprints of the books of Dr. Miller have made money for some one. In all probability, not one cent of their earnings has ever found its way back to the author. Well may it be said of the American publishers of English books, "Other men labored, and ye are entered into their labors." Would it not be well for those who have accumulated fortunes by the publication of the works of Professor Miller and his colleagues to offer to his memory tithes from the storehouses filled by his toil?

WE learn from Boston that the Medical Department of Harvard University has just become the possessor of a large and valuable museum of models of diseases of the skin, the munificent gift of Dr. Edward Wigglesworth, of Boston, a gentleman well known in connection with the dermatology of the present day.

The collection embraces some two hundred models, the work of J. Baretta, of Paris, who is recognized throughout Europe as a most successful modeller and artist. The museum represents models of all of the commoner diseases of the skin, as well as a large number of rare forms, copied from the St. Louis Hospital collection. As works of art and accurate representations of disease, the pieces are remarkably fine, and portray the various affections in a most truthful manner. This is the largest and in fact the only complete museum of the kind in our country; and we congratulate Harvard upon being the recipient of such a generous donation from an individual.

WE learn from a recent exchange that the English government is offering iron hospitals to various unions throughout Ireland for the sums of £220 to £250 and £280, according as they are to contain twelve or twenty patients. They can be set up and made ready for occupation in a month, and are said to be with water-closets, nurse-rooms, wash-rooms, etc., complete. If they be what they seem, these iron hospitals appear to solve the question of hospital construction, costing, we should suppose, furnished, not more than one hundred dollars a bed.

In the abstract of Dr. Flagg's paper, p. 56 of our last issue, *cervical* twice occurs where it should be *crucial*.

CORRESPONDENCE.

MILLER MEMORIAL HOME.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES.

DEAR SIR,—Nearly two months ago I received from Dr. A. G. Miller, son of the late Professor Miller, of Edinburgh, a copy of the subjoined circular, inviting the co-operation of the medical profession of the United States in furtherance of the object therein stated.

In consequence of absence from the city and of various pressing engagements, I was reluctantly compelled to remain silent until the present moment. I now call the attention of my professional brethren to the subject, and sincerely hope that the appeal will meet with a prompt and hearty response.

There is the strongest reason why such an appeal should be generously met on this side of the Atlantic. For nearly a quarter of a century the surgical writings of Dr. James Miller, for many years Professor of Surgery in the University of Edinburgh, were the text-books of the medical students of our schools, and the works that were daily consulted by our practitioners, not only in cases of emergency, but as a part of their daily reading and contemplation. Both his "Principles of Surgery" and his "Practice of Surgery," edited by Dr. Sargent, of this city, passed, if I mistake not, through four editions in this country, and enjoyed for a long time an unbounded popularity. Even at the present moment they are used as text-books in several of the American schools of medicine. It is not too much, then, to say that the family and friends of Prof. Miller have a substantial claim upon our gratitude. But this, although a very important one, is not the only reason why we should extend a generous hand to this praiseworthy enterprise. Every contribution that is made in aid of such an object in behalf of a British professional brother at once assumes the character of an international courtesy, and, as such, it cannot fail to strengthen the bonds of good fellowship between the two nations.

The late Prof. Miller was not only a great writer and teacher, but a most accomplished practitioner, a Christian gentleman, and a warm-hearted philanthropist, never wearying in his efforts to suppress vice and immorality, and to improve the condition of the humbler classes of people in his own and in foreign countries.

Subscriptions may be remitted directly to Edinburgh, to the address of Dr. A. G. Miller, or to Dr. Barton, to my care, Eleventh and Walnut Streets. Medical journals, friendly to the object, will please copy.

I have the honor to be, very respectfully, your friend and obedient servant,

S. D. GROSS.

PHILADELPHIA, October 15, 1873.

"MILLER MEMORIAL HOME."—Shortly after the death of Prof. James Miller, a few friends raised, by private subscriptions, about £1600 as a memorial to him. Knowing the late Professor's long connection with, and deep interest in, Medical Missions, this sum was given towards

the purchase of 56 George Square, as a 'Home' for the students while being trained by the Edinburgh Medical Missionary Society as Medical Missionaries. This sum, however, was short of the purchase-money by £700. Since getting the house, the directors have had to spend more than £300 additional, in necessary improvements and repairs. They now appeal, therefore, to the public, for £1000 to enable them to clear off all debt upon the house, and to establish it as really the 'Miller Memorial Home.' Should more than the thousand pounds be received, it is proposed to place a suitable portrait or bust of the late Prof. Miller in the 'Home.'"

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

OCTOBER 6, 1873.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

PRESENT—Drs. J. G. Hunt, McQuillen, Tyson, W. Hunt, and Richardson.

Visitors—Dr. Leffmann, Mr. C. E. Betticher.

Dr. J. GIBBONS HUNT exhibited specimens of, and made an important verbal communication respecting, the curious alga which polluted the reservoir of the Camden Water-Works last summer. During the course of his remarks he observed, "In July last the water in the basin at Camden, New Jersey, was found to be unfit for use. When drawn from the hydrants it was offensive to both taste and smell. On examining this water with the microscope, I found in it a plant, belonging to the Nostochaceæ, diffused in great abundance through the fluid in gelatinous masses of an opalescent or faint olive-green color. These jelly-like masses were much broken up, indeterminate in form, and enveloped innumerable spiral and brittle filaments, each having from three to fifteen turns.

"Cells of two kinds make up the filaments of this plant. Several subquadrate cells, about $\frac{1}{8000}$ of an inch in diameter, are arranged in linear series; then, at nearly regular intervals, globular cells—perhaps heterocysts—of equal size, and about the same diameter as the other cells, are interposed. Both kinds of cells are filled with granular contents. Owing to the extremely brittle character of the filaments, it was impossible to tell how many spirals completed an adult plant. If placed in pure water, all the cells became quickly separated, and the ripest exploded like miniature bombs, scattering their granules all round. This made it very difficult to preserve a specimen. By using a medium of the same density as the gelatinous water, I have succeeded in preserving a slide of this interesting plant, which I exhibit to the Section, quite unaltered in appearance.

"It is possible this plant is the same that Mr. Thompson found in Lake Ballydrain, near Belfast, Ireland, and described as *Trichormus Thompsoni*, in the *Mag. Nat. Hist.*, vol. v., 1837. It is characteristic of the Nostochaceæ to increase with great rapidity under peculiar conditions. During June of this year, little or no rain fell on the Camden basin for nearly thirty consecutive days, and the sun shone with almost unobstructed power on the still surface of the water. I venture to mention the subject at this meeting, because I am not aware that the plant has been found before in this

country, and there are no correct figures of it in the books."

Dr. WILLIAM HUNT inquired if any diseases were especially prevalent in Camden at the time this alga made its appearance and flourished in the reservoir.

Dr. J. G. HUNT did not know of any which prevailed to an unusual degree.

Dr. JAMES TYSON asked if Dr. HUNT could suggest any remedy for the exuberant growth of this plant.

Dr. J. G. HUNT replied that the only one which had occurred to him was the plan of continued agitation of the water, as, for example, by forcing it to the top of a tall stand-pipe and letting it overflow into the basin from a considerable height, thus mechanically breaking up the spirals of the alga and interfering with its growth.

Dr. J. G. HUNT also showed the inosculating vessels in a leaf of the *Euphorbia ipsecacuanha*, and likewise a series of receptacles in the same plant, reminding one of the air-cells of the lung. He remarked that he exhibited them as specimens of a new style of work (the method for which he would lay before the Section when perfected), that would do away with much of the labor of dissection, and display vegetable structures in a unique manner, which he believed could not be equalled in Europe or America.

Dr. RUSCHENBERGER inquired whether drawings or photographs had been made of the beautiful specimens brought before the Section by Dr. HUNT.

Dr. HUNT replied that no drawing or photograph could do justice to the views of these objects as afforded by the invaluable binocular microscope.

Dr. J. G. RICHARDSON suggested that by taking a photograph through each tube of the binocular microscope and afterwards combining these two pictures by looking at them in the ordinary hand stereoscope, we would secure a perfect and complete reproduction of the exquisite image in relief obtained by the aid of double-tubed instruments, and he recommended that the method should be tried at an early opportunity.

REVIEWS AND BOOK NOTICES.

ON THE MECHANICAL TREATMENT OF DISEASE OF THE HIP-JOINT. By CHARLES FAYETTE TAYLOR, M.D., Surgeon to the New York Orthopædic Dispensary and Hospital, etc. New York, William Wood & Co., No. 27 Great Jones Street, 1873.

A practical book, by an intensely practical man. Guilty of no useless verbiage, indulging in no flowers of rhetoric, at times perhaps even doing violence to strict methods of construction, the author marches straight to his end, possessing the not trifling merit of making himself, as a rule, thoroughly understood.

His first chapter plunges incontinently into statistics derived from the hospital and dispensary of which he is chief, as well as from his private practice, from which he deduces the result, founded on the carefully-collected histories of about four hundred cases, that "disease of the hip-joint, at least so far as regards the mechanical treatment, may be regarded as essentially traumatic." This view has been maintained for a number of years past by Dr. Sayre, and is put forth with much vigor in Dr. Louis Bauer's Lectures on Orthopædic Surgery. New York surgeons have indeed very generally adopted it. Its importance in relation to both prognosis and treatment cannot be overestimated; and the sooner we of Philadelphia make it a part of our creed, renouncing our antiquated notions of the necessary dependence of chronic affections of this or indeed of any articulation on a pre-existing strumous diathesis, the sooner shall

we be able to claim for ourselves the credit of an intelligent conservatism in their management.

While justly according to Dr. Henry G. Davis, of New York, the merit of being the first to combine locomotion with extension in the treatment of hip-disease, Dr. Taylor considers the splint which that surgeon uses inefficient. The advantages which he claims for his own modification are, that in reaching to the ground it entirely prevents concussion of the joint in walking, that in extending the entire length of the limb it controls its movements and accomplishes its extension much more effectively, and that by a special adaptation it overcomes adduction as well as flexion of the thigh upon the pelvis. These points appear to us to be well taken. In our own experience we have found all of these modifications to be of the greatest possible advantage; but, at the same time, it must be confessed that Prof. Sayre's splint has, in his own hands, been productive of results which scarcely warrant the severe strictures which our author passes upon it. These successful results are, no doubt, in a great measure attributable to the extreme care with which Dr. Sayre applies his adhesive straps and his admirable method of in-and-out bandaging. It is safe to say that few surgeons can use it with the same success.

The gist of the present little monograph, that which affords the justification for its publication, without which no author should dare to show his face, appears to consist in the attempt to methodize the process of extension, dividing it into stages which are the exact reverse, in point of order, of the stages of the disease, thus making it both easier and more complete; attempting for the distorted coxal articulation what Mr. Adams accomplished for the distorted tarsal articulations in talipes varus. He, it will be remembered, proposed to divide the treatment of that affection into two distinct periods, one of which should always be perfected before the second was begun.

Those who have conscientiously followed this plan, overcoming the lateral distortion by force directed through the transverse tarsal joint before attempting to bring down the heel by force directed through the ankle-joint, do not need to be informed of its superiority over the old, blundering method, which attempted all at once. Dr. Taylor does not tell us whether he derived the inspiration for his suggestion from Mr. Adams or not, but the similarity in the two modes of procedure is certainly close and suggestive. The two separate sets of muscles which produce distortion and demand extension in hip-disease are the adductors and the flexors. As the former have been the last to become contracted under the influence of the irritation in the joint, our author considers that they should first be relaxed, and that only when that object is effected can we hope to act with the greatest amount of efficiency on the latter. In order to accomplish this, he places the diseased limb on an inclined plane reaching below the foot and exactly adapted to its deformed position. To the limb thus supported and flexed he applies his splint, and (the patient retaining the dorsal decubitus) commences abduction by means of a powerful screw. When abduction is an accomplished fact, whether that be at the end of an hour, a day, or a week,—the last-mentioned being the longest period of time which he has found necessary to devote in ordinary cases,—he is ready to begin to lower his inclined plane and thus overcome the contraction of the flexors. The application of the splint of course assumes the employment of a certain amount of extension. The entire process of overcoming these contractions may occupy in difficult cases a fortnight. At the end of that time relaxation is complete, and all that we need is to keep up vigorous extension, allowing the patient perfect freedom of motion through the joint, an essential to a

return to a healthy condition. By this means, he claims, a resort to tenotomy is almost never necessitated. Our own practice is to overcome the contractions by means of forcible manipulations under anæsthesia, and immediately apply the splint and allow locomotion. We have had reason to feel tolerably well satisfied with the results thus obtained; but the plan here proposed is rational and scientific, and the author's acknowledged success should certainly lead to its having a fair trial. There are numerous practical apothegms scattered through the sixty-two superbly printed pages which the seven brief chapters of the work occupy, which we would gladly quote and enlarge upon did space permit. The illustrations are very unequal both in design and execution, but generally serve to convey the desired idea. What is unfortunately very unusual in an American medical work, they are all original. We would call the author's attention to the fact that Fig. 13, which is referred to on page 36 as representing the appearance of the instrument when applied, places it outside of the shoe, which we take to be an error.

THE DISEASES OF THE PROSTATE: THEIR PATHOLOGY AND TREATMENT. Comprising the Jacksonian Prize Essay for the Year 1860. By SIR HENRY THOMPSON. Fourth Edition. Philadelphia, Henry C. Lea, 1873.

The appearance of the fourth edition of this standard essay is proof that monographs of the higher order are not always the barren waste of "meritorious energy" that Dr. Tilt would have us think. Certainly few prize essays have been more highly prized and praised. The distinguished author informs us in the preface to the present edition that he found it necessary to make several additions, at the same time compressing existing material. We have always deemed the essay a model of its kind. It is terse in style, rational in method, and thorough in all its parts. From original anatomical work the writer passes easily to the consideration of morbid changes and their treatment. In no other volume that we recall is there to be found so good a description of acute prostatitis or abscess of the prostate gland. The same remark is applicable to the changes in the urethra from prostatic hypertrophy. Perhaps the most original chapter is the one entitled "The effects of enlarged prostate in relation to the function of micturition, retention, incontinence, engorgement, and overflow." This subject has received masterly treatment throughout; and one naturally refers to it as the best authority. The allusion to the internal meatus of the bladder, particularly to the instructive morbid appearances therein located, is provokingly insufficient. It would have been a point gained, in our opinion, had our author emphasized the direction which is too little heeded by pathologists,—viz., to open the bladder at its summit, in examination of all suspected lesions of the genito-urinary tract, prior to making the destructive incision along the urethra.

THE PREVENTIVE TREATMENT OF CALCULOUS DISEASE, AND THE USE OF SOLVENT REMEDIES. By SIR HENRY THOMPSON. Philadelphia, Lindsay & Blakiston, 1873. 8vo, pp. 72.

The little book before us is a reprint of two lectures given at the University College, London. The first lecture treats of the early history of calculus and its treatment: the second, of the treatment of stone in the bladder by solvents. After giving a brief résumé of "all the nauseous mixtures described from Pliny to Joanna Stephens and onward through Chittick, with his locked cans, to the nostrum-dealers of our own times," the writer states as his opinion that the most rational hope of success is secured in the early stages of uric acid calculus when by the liberal use of the salts of potash

—notably the citrate and acetate—the symptoms of nephritic and cystic calculus may be ameliorated, and in some cases entirely disappear.

SELECTIONS.

ALBUMINOUS EXPECTORATION.

II.

LET us pass on to the opinions enunciated by MM. Woillez and Marrotte, and see if *traumatic perforation* can give the key to albuminous expectoration as a result of thoracentesis. Woillez, in his *Traité des Maladies Aigues des Organes Respiratoires*, pronounces the opinion that puncture of the lung in thoracentesis is more common than is usually supposed. At the meeting of the Société Médicale des Hôpitaux on June 28, he dwelt upon the fact of recent puncture of the chest; on the physical and chemical similarity of the fluid extracted from the pleura to that expectorated; on the issue of a small quantity of blood by the canula; and, above all, on the presence of blood in the earlier portions of the expectorated liquid; finally, on the issue of bubbles of air through the canula during the course of the operation. He attributed the mischief to the operation itself, consisting as it does in plunging a sharp instrument more or less roughly and directly into the chest, without knowing, says M. Woillez, whether the lung be floating or not in the liquid, and whether it do not advance to meet the point of the instrument, and, likewise, not knowing if some local adhesion do not retain it within reach of this point. M. Woillez considers one of the best proofs of the lesion of the lung by the trocar to be more or less rapid expectoration, after puncture, of a fluid resembling that extracted from the pleura; and amongst the outward characteristics he cites one having a particular value in his eyes,—namely, that the expectorated fluid may be sanguineous. In the cases under consideration, however, not one of the true signs of perforation was noted; neither issue of blood through the canula, nor passage of air from the bronchial tubes into the pleural cavity by pneumothorax, is spoken of. MM. Marrotte and Woillez have never demonstrated any perforation, nor has any ever been found on necropsy. It is, besides, as pointed out by M. Hérard at the meeting of July 11, 1873, necessary to know if effusions followed by sero-albuminous expectoration were small effusions, and if the lung may have been injured during the operation. But, in M. Terrillon's twenty cases, in three only from one hundred to fifteen hundred grammes of fluid were removed; whilst in the others the amount rose from two thousand to five thousand five hundred grammes. Therefore, in the majority of cases the lung was removed from the thoracic wall, driven back to the vertebral column, and thus sheltered from the point of the trocar. M. Béhier points out, in his lecture on June 13, that it is an incontestable fact that if the albuminous expectoration arose from perforation it would not take an hour to come on: it would be as immediate and instantaneous as the injury itself, as in Boule's case already mentioned. In that case, the lung would have been wounded four times in succession, notwithstanding that every precaution against such an accident was taken. It is evident that this cannot be the fact, and consequently perforation of the lung by the trocar may be put aside.

We now come to the third explanation,—the *passage of the pleural liquid into the pulmonary vesicles, and thence into the bronchial tubes*. This will not detain us long, for it is acknowledged to be impossible; it is con-

traded by the anatomy of the lung, and by the physiology of combined absorption and circulation, which teach us, as M. Terrillon says, that the fluid passes into the vessels and is carried into the general circulation. Why, then, should not the pleural liquid be submitted to this physiological law? Besides, in bringing forward this explanation, the fact that the pleura loses its absorbent properties when it is inflamed and becomes covered with false membranes, is entirely lost sight of.

We now come to the fourth explanation, enunciated by M. Pinault in 1858, and repeated with much clearness and force by M. Hérard in 1872,—the *transudation of the sero-albuminous liquid through the alveolar walls* by means of rapid pulmonary congestion with pulmonary œdema. This is based on sound physiology and on pathological phenomena, and is upheld by the majority of physicians, MM. Hérard, Moutard-Martin, Béhier, Dujardin-Beaumetz, Brouardel, and others, and is demonstrated by clinical observation and necroscopic examination. Physiology explains this transudation as follows. Section of the pneumogastric nerves brings on a frothy effusion in the bronchi and a sanguineous engorgement of the pulmonary tissue. One of the two products of secretion is nothing but bronchial mucus; the other, which is most abundant, is serous matter. M. Jaccoud, touching on the œdema of congestion, in his *Elements of Internal Pathology*, says, "constituted by a serous exudation in the walls and on the free surface of the alveoli, œdema is the constant and necessary consequence of all pulmonary congestion of a certain standing." M. Charles Robin, in his *Traité des Humeurs*, acknowledges that the capillary network of the surface of the alveoli may, under the influence of either temporary or permanent congestion, allow a certain amount of fluid quite distinct from the bronchial mucus to exude. M. Moutard-Martin grapples with the question in a very clear and decided way. "You cannot," he remarks, "clinically establish your so-called pulmonary perforation, while on our part we do clinically establish the sero-sanguineous congestion of the lung, by the presence of slight dulness and subcrepitan râles, of pulmonary œdema and hæmoptysis." That it may be proved after death is shown in M. Gombault's case reported by Terrillon. In the explanation of this transudation, it is easy to understand that, when a lung has been compressed for a certain time, when it has been excluded from the air, that natural excitant, penetrating rather suddenly into the pulmonary vesicles, would produce irritation of the mucous membrane, and an excitement of the vessels which in a very short time would be followed by paralysis, of which the inevitable consequence is passive congestion with œdema. If we add to this the destruction of the epithelium which clothes the alveoli and strengthens the walls of the capillaries, the probability of MM. Hérard's and Moutard-Martin's explanation will be much increased.

In certain cases of albuminous nephritis, the desquamative congestion at the commencement allows the capillaries of the kidney to let the albumen escape into the tubules and mix with the urine; here the modified alveolar mucous membrane readily allows the albuminous serosity to filter through. Further evidence of the rapid congestion of pulmonary œdema, and of the expectoration resulting from this œdema, may be found in the analysis of the two fluids. The very complete researches of M. Dujardin-Beaumetz show that these fluids have a very distinctly marked difference of character. He says, "while both fluids contain urea, mucine, and albumen, the expectorated fluid only contains 1 part in 1000 of albumen; the other, on the contrary, contains from 66 to 88 parts in 1000. This difference in the analysis," says M. Dujardin-Beaumetz, "includes, in our opinion, the difference in the origin;

and we can now affirm that the expectoration is exclusively derived from the bronchial mucus."

Further, in favor of the theory of pulmonary congestion as an etiological condition of the accident in question, the different cases of albuminous expectoration after thoracentesis, observed by M. Louis Lande, Professor in the Bordeaux School of Medicine, must be recorded. He proves the non-identity of the two fluids in a decisive manner by citing the cases of Dr. Musson and Dr. H. Gintrac, in which the phenomenon came on after thoracentesis, performed for purulent effusion. To this may be added the conclusive proof given by MM. Revillout, Jalabert, Renan, etc. M. Revillout has applied himself specially to this subject; and the series of investigations which he has published in the *Gazette des Hôpitaux* for June and July are calculated to throw much light on this interesting problem. They are on very simple cases, attacks of albuminous expectoration not only arising without any thoracentesis, but even without the presence of any pleurisy.

In a series of clinical records, M. Revillout has accumulated a progressively significant number of cases, which, from their great theoretical and practical interest, deserve to attract the attention of physicians. In one of them, an old man, subject to attacks of asthma, did not at the time suffer, nor had ever suffered, from pleurisy. On two occasions he was seized with alarming crises, characterized by a cough, which at each expiratory movement brought up a mouthful of albuminous fluid tinged with blood, with which the patient soon filled a large basin.

In a similar case, M. Jalabert, of Carcassonne, rejecting all idea of a pleural origin for the fluid, especially as the patient was subject to similar attacks from time to time, which were completely relieved by bleeding, did not hesitate to diagnose pulmonary congestion with excessive bronchial secretion, and combated the attack by agents capable of exciting the contractility of the small vessels, such as ergotin and syrup of belladonna.

These cases, M. Revillout remarks, lead us to form more just notions of acute pulmonary œdema. Similar cases have also been described by Robert Bree and Laennec. These accidents are not brought on by asthma only; for Dr. Renan, of Saumur, gives a report of a similar case which might perhaps be considered as a manifestation of paludal infection. It is, then, to the fourth explanation of the phenomenon of albuminous expectoration that the balance of evidence inclines. The subject is one of great clinical interest, and deserves the attention of medical observers, with a view to the definitive solution of the question at issue.—*British Medical Journal*, October 11.

GLEANINGS FROM OUR EXCHANGES.

TREATMENT OF ENURESIS (by Dr. Buyelmann, of Cologne).—The author was induced by an article in the *Berlin. Klin. Wochenschrift*, 1871, No. 5, to try the syrup. ferri iodidi in a severe case of incontinentia urinæ. The patient was a young girl, thirteen years old, of nervous temperament, and anæmic. The principal complaint was the incontinence of urine, so severe as to prevent her from walking any distance from her home without wetting herself. In addition to generous diet, she took, for three weeks, syrup. ferri iodidi, seven grammes, ad aquæ, syrup. simp., aa fifty grammes; a teaspoonful every two hours. After a week's treatment there was a marked improvement, and in two weeks more she was discharged well.—*Berlin. Klin. Wochenschrift*, No. 6.—*Boston Med. and Surg. Journal*.

EXOPHTHALMIC GOITRE.—Boddaert (*Bull. de la Soc. de Méd. de Gand, Gaz. Méd.*, 1873, p. 141) experimented on rabbits with reference to the origin of this condition. Ligatures were placed upon the external and internal jugular veins at the base of the neck, and the two cervical cords of the sympathetic were cut. An exophthalmia resulted, continuing several days, diminishing gradually as the collateral venous circulation became developed and as the effects of the section of the sympathetic disappeared. Exophthalmia following the ligature alone, due to distention of the orbital veins, is much less pronounced. An enlargement of the thyroid is produced by section of the sympathetic and ligature of the inferior thyroid vein between the four jugulars. These experiments, combined with the discovery of lesions of the sympathetic, whose effects are analogous to those produced by section (atrophy of nerve-elements, hypertrophy of connective tissue) in a number of cases of Basedow's disease, are considered as explaining the phenomena of the disease. In exophthalmic goitre, an obstruction to the circulation occurs; the superficial veins, especially of the neck, become swollen; there is a tendency to hemorrhage, an increase of splenic and hepatic dulness, occasional dropsies, œdema, and the enlargement of the retinal vessels observed by Graefe. Boddaert hence produces this theory of exophthalmic goitre. In the majority of cases the pulsations of the heart increase in number,—120 to 200 even; this may continue for months. The veins are insufficiently emptied during the diastole; a venous congestion results, more marked from a more or less complete paralysis of the sympathetic. The effects become most marked in the eye and thyroid body, from the development of the retro-ocular venous system and the great vascularity of the thyroid. This theory is considered as explaining the observation of Trousseau, where the exophthalmia and the thyroid tumor came on during a night, the goitre disappearing suddenly and returning afterwards; also, the diminution of the exophthalmia and the thyroid body, as the heart beats less rapidly.—*Boston Medical and Surgical Journal*.

THE ELECTRO-MAGNETIC CURRENT IN THE SECOND STAGE OF LABOR (*Edinburgh Medical Journal*, September, 1873).—Dr. A. E. McRae details three cases of *inertia uteri* in which the use of galvanism was attended with very happy results, bringing on contractions when they had ceased entirely, hastening delivery, facilitating the discharge of the placenta, and counteracting a decided tendency to post-partum hemorrhage. He believes that this agent should be employed when the os is dilated or dilatable; when the uterine action has ceased, and cannot be aroused by stimulants, friction, or other oxytoxic agents; when there is evidence of uterine action becoming weak, irregular, or intermittent; and when there is post-partum flaccidity of the uterus, or post-partum hemorrhage not caused by hour-glass contractions. The method of application is as follows. One of the electrodes is applied to the abdominal parietes, and retained by the patient's hands, with a layer of blanket between, to prevent the current entering by the finger. The other pole is placed against the perineum, and retained by folds of blanket or a small pillow. The force can be moderated or increased at will by the left hand of the accoucher working the "regulator" while the right hand manipulates the child's head. The electrodes are now attached to the machine, the current is set on, and, in obedience to a law in electro-physics, takes the shortest and most direct route from the abdominal to the perineal electrode, or *vice versa*. The uterus lying in this direct line shares in the influence, its fibres contract, and in so doing aid in expelling the uterine contents; its action

being limited by the electric force evolved, the quantity and condition of the muscular fibre of the uterus, and the patency of the passages. When the head descends and comes towards the perineum, the perineal electrode should be shifted to the coccygeal region, thus exercising a *vis a tergo*, and, by relieving the perineal muscles of their tonic contractions, allowing them to become flaccid and permit dilatation. The head is thus born in the proper line of the axis of the outlet with freedom.

DIGITALIS IN ACUTE FEBRILE DISEASES (*The Practitioner*, September, 1873).—The question of the power of digitalis as a heart tonic in the adynamic fevers is a very important one, and is becoming more so as we recognize the frequency with which sudden failure of the heart is a cause of death in diseases running a protracted course, or occurring in subjects whose tissues were damaged by disease or intemperance.

Dr. Anstie believes that we are entitled to view muscular heart-failure in acute febrile diseases as essentially dependent upon an enforced rapid action, under high temperature, prolonged for a period which is excessive in proportion to the vital recuperative power of the cardiac muscular tissue. The same result will be produced in a shorter period if the tissues of the heart have been previously so modified by pathological degeneration as to render their restoration to a healthy state unusually difficult. The practical effect at which we should aim in such cases, merely for the sake of preserving the soundness of the muscular tissue, if for no other reason, is the simultaneous slowing and strengthening of the ventricular contractions; and clinical experience has shown that this effect may be most safely and surely produced by the use of digitalis.

Dr. Grimshaw has given one and a half ounces of the infusion of digitalis every three hours for five or six days together, not only with impunity, but with seeming benefit, in some cases of typhus fever; Wunderlich has administered daily thirty to fifty grains of the powdered leaves; and Trousseau in uterine hemorrhage has given in twenty-four hours one gramme (15.6 grains) of digitalin, the normal dose of which is from $\frac{1}{4}$ to $\frac{1}{2}$ of a grain. The true explanation of the tolerance of such enormous doses must be sought in the experiments which have shown that the real action of digitalis on the heart is that of a stimulator, instead of a paralyzer, of the cardiac muscular substance, which, weakened and exhausted by over-work, high temperature, or profuse hemorrhage, would sustain and even require a dose of digitalis merely to support a sufficient amount of contraction to continue life, which dose in health would fatally tetanize the heart.

OIL OF TURPENTINE AN ANTIDOTE IN POISONING BY PHOSPHORUS (by Hermann Koehler. [Note by K. B. Hofmann, in *Med.-Chirurg.*, Rundschau, June, 1873. Translated for the *Detroit Review* by J. Henry Carstens, M.D.]).—The author published (after he had brought his discovery to the notice of the profession) his observations in a paper, "The Value and Significance of the Oil of Turpentine containing Oxygen in Phosphorus Poisoning, etc. Halle, 1872." He sums up the result in the following sentences:

Oil of turpentine containing oxygen is a reliable antidote of phosphorus.

The kind of turpentine, if of this or that species of pine, if German or French (in opposition to Vetter's statement that only the latter has antidotal powers), is of no importance, if it has only not been rectified for some time, and contains oxygen.

The oil of turpentine *only* acts in the *stomach*, and is best introduced by gelatin capsules; to emulsify the turpentine oil with the yolk of an egg is not advisable, as the latter contains the oil of the egg, which facili-

tates the solution of the phosphorus. For every 0.01 gramme of phosphorus *one* gramme of oil of turpentine as an antidote is sufficient.

The turpentine must be administered as soon as possible after the poisoning. Twenty-four hours after the introduction of the phosphorus the oil of turpentine does not act.

The beneficial action of the antidote is due partly to its containing free oxygen for changing the poisonous phosphorus to the non-poisonous phosphoric acid, and partly by combining with the phosphorus to form the turpentine-phosphorous acid, which is not injurious. This acid, which is only dangerous in very large doses, appears (like laurin and turp. oil camphor) to be eliminated unchanged by the kidneys. It and its salts rapidly absorb oxygen from the air, and oxidize to a resinous derivative of the oil of turpentine, containing phosphoric acid, and this rapid oxidation has prevented an analysis for the ultimate elements.

TAPPING IN HEPATIC ASCITES (*Dublin Journal of Medical Science*, August, 1873).—Dr. John M'Crea reports two cases of ascites which were greatly benefited by repeated tapplings. In the first case the disease was of a rachitic nature, and the treatment, in addition to the withdrawal of the fluid, consisted of the free administration of sal-ammoniac. In the second, diuretics and purgatives failed to make any impression; the operation was repeated fifteen times, and about forty gallons of fluid were withdrawn from the patient. In both cases the accumulation of fluid ceased, and was followed by almost perfect restoration to health.

Dr. M'Crea claims the following advantages for early tapping in hepatic ascites:

1. It relieves intra-portal pressure, and prevents the backward pressure generated by the obstruction from seeking vent in diarrhœa, hemorrhoids, hæmatemesis, etc.
2. The removal of the pressure which the effusion exercises on the liver will facilitate the development of collateral circulation through the more healthy parts of the viscus.
3. The relief of the abdominal tension will make it easier for the vena cava, vena azygos, and parietal abdominal veins to establish a collateral circulation between the abdomen and the chest.
4. The removal of tension from the vena portæ and its branches will promote the absorption of remedies.
5. We clear away an impediment to the digestion and absorption of nutriment.
6. We relieve the kidneys, which exhibit increased activity after each tapping.
7. In ordinary cirrhosis we remove a pressure which is assisting to produce contraction.
8. We afford relief to other important organs, the distress of which makes tapping at least an absolute necessity.
9. We avoid the danger of typhoid peritonitis, which sometimes attends late tapping. Finally, we may hope for better results in liver dropsy by looking on tapping not merely as a palliative, but even as a radical, method of treatment.

SUCCESSFUL (?) REMOVAL OF THE SPLEEN.—In the *Raccoglitori Medico*, Dr. Sonsino gives an account of a case in which, on June 20, Dr. Attilio Urbinato of Cesena removed a hypertrophied and mobile spleen. The incision was made in the middle line, and prolonged above the umbilicus, being at least seven inches in length. The operation was performed without much difficulty. After tying three small cutaneous arteries, opening the peritoneum, and drawing aside some loops of intestine, the spleen was seen, free from all abnormal adhesions, and of enormous size. At the inferior part was seen the gastro-splenic epiploön, which was adherent; and

the vessels here were extremely dilated. At the upper part was seen the lower portion of the pancreas. The epiploön was detached, and the vessels tied. The ligatures, seven in number, were left inside without further precaution. The few adhesions of the pancreas were overcome without difficulty, simply by means of the finger. The largest vessels, and the connective tissue which surrounded them, were secured by a metallic loop and hempen ligature. The "toilette" of the abdominal cavity was made with great care. The patient lost but little blood. The ligatures of the vessels tied were passed out between the sutures, of which there were five deep and five superficial. The spleen weighed two and a half pounds. The operation lasted an hour; the patient bore the chloroform well, and subsequently appeared to be progressing favorably, but died of peritonitis three days after the operation.—*British Medical Journal*.

SYPHILITIC ALOPECIA.—That form of syphilitic alopecia which is independent of any eruption affecting the scalp, which accompanies the so-called secondary syphilides, and which is characterized simply by an extensive loss of hair, so that the greater portion of the scalp is denuded absolutely of hair, and not the scalp only, but also the eyebrows and eyelids (of eyelashes) as well, is often a persistent affection, and in my experience is only—very tardily, indeed—remediable by general (mercurial) treatment. I refer to the condition described above, as distinguished from the syphilitic alopecia, resulting commonly (in tertiary syphilis) from the limited and "discrete" loss of hair resulting from the formation of cicatrices consequent on (tertiary) syphilitic ulceration of the scalp. This kind of alopecia, which has by some eminent French writers been assumed to be identical with tinea decalvans (la teigne pelade), but which is to be distinguished from any even the most "diffused" forms of the latter disease by its want of definite limitation of margin, is, as I have found, readily (within a month or so) curable by the following topical remedies:

For the scalp, hydrargyri iodidi rubri, gr. v; attar. rosæ, ℥ij; olei amygdalæ, ℥x; unguenti simplici, ʒj.

For the eyebrows (where the skin is more tender), three grains of the mercurial iodide are used. The prescription is otherwise the same as before.

For the eyelids, which are more tender still, five grains of the yellow oxide of mercury, made by the recent method, are substituted for the iodide. The prescription is otherwise as above.

The French writers referred to regard secondary syphilis as merely a predisposing cause of tinea decalvans. I, however, regard the "secondary" syphilitic alopecia as a distinct disease.—*Balmano Squire, M.B., in British Medical Journal*.

A WAX CANDLE IN THE BLADDER OF A FEMALE.—This interesting case was observed a short time ago at the Hôtel-Dieu, Paris. The patient, on admission, complained of intense pain in the abdomen. The urethra, abnormally dilated, easily admitted the finger into the bladder, when a hard, voluminous body was felt. The woman stated that, on account of great difficulty in making water, she had passed a candle through the urethra and had accidentally let it slip into the bladder. It was readily removed with a pair of pincers. The end of the candle, which had been rounded with a knife, was covered with calcareous matter gathered there during the five weeks the candle had stayed in the bladder. Speedy recovery followed.—*Boston Medical and Surgical Journal*.

TOMATO-LEAVES AS A DIURETIC.—A French writer extols the leaves of the tomato (*Solanum Lycopersicon*) as a diuretic.—*Pacific Medical and Surgical Journal*.

PITURI.—A NEW NARCOTIC.—Dr. Bancroft, in a paper read before the Queensland Philosophical Society, enumerates the effects of the leaves of the "pituri," which are used by the natives as a stimulating narcotic in a similar manner to the betel of the East, and which form a substitute for tobacco. After detailing some experiments made with an infusion of the leaves, he thus describes their results:

"1. Period of preliminary excitement from apparent loss of inhibitory power of the cerebrum, attended with rapid respiration; in cats and dogs, with vomiting, and profuse secretion of saliva.

"2. Irregular muscular action, followed by general convulsion.

"3. Paralysis of respiratory function of medulla.

"4. Death, or

"5. Sighing inspirations at long intervals.

"6. Rapid respiration and returning consciousness.

"7. Normal respiration and general torpidity, not unattended with danger to life."

The poison, given by the mouth, acts with less vigor; when it is injected into the intestines the results are more certain. The animal has a longer stage of excitement, the convulsive fit is not so severe, and recovery is more certain. Torpidity remains for some hours.—*London Medical Record*.

ATROPIA IN STRYCHNIA POISONING (*Edinburgh Medical Journal*, September, 1873).—Mr. Samuel Buckley reports the case of a female, æt. 28, who for the purpose of suicide took an indefinite quantity of a patent "vermin-destroyer" containing strychnia. When she was seen, a half-hour later, she was in a state of perfect opisthotonos, with severe and painful spasms at exceedingly short intervals. Treatment was commenced by the inhalation of chloroform, but, this proving useless, atropia was injected subcutaneously, one-sixth grain every ten minutes, until three doses were given. A marked improvement resulted; the spasms grew milder and less frequent, and the expression more natural. The atropia was then given in doses of one-twelfth grain at longer intervals, until $1\frac{1}{2}$ grains had been administered. She then became conscious, the spasms ceased entirely, she fell into a profound but natural sleep, and after awaking suffered no further inconvenience.

The effects of the atropia were so marked in mitigating and counteracting the symptoms that no hesitation was felt in using the very large doses which have been mentioned.

RUPTURE OF THE BLADDER.—Dr. MacEwen reports the case of a lad, nineteen years of age, who had been habituated to excessive indulgence in alcohol, and who died suddenly during a debauch, having had no unusual symptoms except slight colicky pains in the abdomen and a desire to lie with his thighs flexed on his belly. On post-mortem examination the whole abdominal cavity was found to be filled with a straw-colored fluid, inodorous and non-ammoniacal. There were no peritoneal adhesions or inflammatory products of any kind. The thoracic and abdominal viscera were healthy, with the exception of the bladder, in which was discovered an aperture at the junction of the upper and middle thirds posteriorly. There were no ulcerations, appearances of gangrene, organic stricture, obstruction, or false passages. The rupture must have taken place either from temporary paralysis of the bladder, or from spasmodic stricture with violent muscular action in the over-distended viscus.—*The Lancet*, Sept. 27, 1873.

WRITER'S CRAMP (*Irish Hospital Gazette*, October 1, 1873).—Professor C. J. Rossander details the case of a strong, muscular man, æt. 32, who had suffered for two years from an entire inability to form letters or to make

any but perpendicular strokes of a pen. He was unable to move his hand towards the ulnar side, and when he attempted to do so the whole hand was forcibly jerked into the air. There was no loss of power in the arm or hand, other movements were normal, and it was only in attempting to form letters, and particularly several in succession, that the spasmodic action showed itself. Treatment was commenced by the daily injection of ten to twelve drops of a solution containing one per cent. of nitrate of strychnia, and by "massage" or the kneading and rubbing of the muscles of the hand and forearm. At the end of a week there was a decided improvement, and in a month the patient was perfectly restored to health.

REMOVAL OF BOTH SUPERIOR MAXILLARY BONES.—The *Centralblatt für die Medicin. Wissenschaft*, for June 21 contains a brief note of a case related by Podraski in the *Oesterr. Zeitschr. für prakt. Heilkunde*, No. 1, 1873, in which he removed both upper maxillæ from a man aged 42. They were the seat of a tumor which had the appearance of being malignant, being attended with pain and swelling of the lymphatic glands. It was, however, found to be a large ivory exostosis, which had almost obliterated the sinuses and nares. The patient died of pyæmia.

COMBINATION FOR CHRONIC DIARRHŒA.—Rayer advocates the combination of cinchona, charcoal, and bismuth in the management of chronic diarrhœa, in these proportions:

R Subnitrate of bismuth, 3j;

Cinchona, yellow, powdered, ʒss;

Charcoal, vegetable, 3j. M. Chart. xx.

S. Two or three times daily during the intervals between meals.—*Union Médicale*, No. 73.

MISCELLANY.

ANECDOTE OF NÉLATON.—A medical writer tells the following little story of the great French surgeon Nélaton. Speaking of a visit to one of the Paris hospitals, he says, "As we passed into the hall we heard groans, evidently of a child in great pain. The door leading to the sick-ward was ajar, and as we approached we heard the voice of a man talking earnestly with a little sufferer. There was something very affecting in the imploring tones of the child's voice and the tender and sympathizing replies of the physician, and it seemed to us no breach of etiquette to witness unseen, through the crack of the half-open door, the scene that was passing within. On a narrow pallet near the window lay a fine boy, nine or ten years old, dying of cancer developing itself between the eyes and behind the nose. It had not shown itself externally, but had destroyed the sight, and was attended with excruciating suffering. By his side sat a stately white-haired man, holding with one hand the two of the little patient, while with the other he caressingly smoothed his hair. The child told the story of his pain, '*Ah, je souffre tant!*' to which the old man listened patiently, promising to devise some relief. Then he rose to go, but first bent over the boy, and, with tears dropping from his eyes, kissed his forehead as lovingly as a mother. The white-haired man was the world-renowned Nélaton, lately summoned to attend the fallen Emperor."

In the recent inquiry into the condition of the Civil Service in Ireland, it was natural that there should be some reference made to the incomes obtained by professional men in this country. Some extracts from the evidence given may be of interest. Dr. E. Kennedy stated that in Dublin a competent medical man, having the advantages of a hospital and connection, ought, when of ten years' standing, to make from £800 to £1200 a year; if reasonably successful, he ought then to double his income in the course of the next five or six years, and a really successful man ought in a few years more to double his income again; but the instances in which a medical man reaches £6000 a year or £5000 are very rare. The advantage of a hospital physician is that his pupils become scattered about the country and send up patients to him. In the chief provincial towns of Ireland, with a large population, the leading medical man may possibly reach from £1200 to £2000 a year. Sir D. Corrigan, who was also examined, thinks there are perhaps ten or twelve medical men in Dublin making from £2000 to £6000 a year, or more; and there are a great number, whose names are not very prominently before the public, making from £800 to £1000 a year. There are general practitioners in Dublin, men who have never written a line, and who are unknown to the public as men of great eminence, who sometimes accumulate large fortunes.—*London Lancet*.

THE great Dr. Johnson, who said in his day a great many wise things, but also several foolish things, and who thought he knew everything, has thus written in his Life of Akenside: "A physician in a great city seems to be the mere plaything of fortune. His degree of reputation is for the most part totally casual: they that employ him know not his excellence; they that reject him know not his deficiencies."

These observations are a bundle of fallacies, and if I think them worth noticing, it is to ask you not to be so mistaken as to believe in them. If you do believe in them, and act on them, you will assuredly repent it. Go through the lives of the eighteen or twenty men included in the volume I have noticed [The Lives of British Physicians, extending from Linacre, in 1410, to Gooch's death, in 1830, a period of about four hundred years], and you will learn this: that, whether they were polished in manners like Linacre and Meade, or boorish like Radcliffe, a staunch royalist like Harvey, or a Roundhead like Sydenham, a very martinet in dress like Jenner, or plain as a Quaker in costume like Sir Thomas Browne, there was one quality which all possessed in common, and that it was which placed fortune at their feet,—unremitting hard work in their early days. They were never the playthings of fortune, as Dr. Johnson foolishly ventured to say: they commanded fortune.—*Sir Dominic Corrigan: London Lancet*.

THERE appears to be a great mortality this season among the English grouse, concerning which a correspondent of the *London Lancet* says:

"All birds I have examined during this or former epidemics contained tape-worm. In May last I obtained

two birds, one from the neighborhood of Kirriemuir, the other from Sir Thomas Gladstone's moor, near Fettercairn. Both were in good plumage; the one was emaciated, the other in good condition. The portion of the intestine above the tape-worm was impacted with dry vegetable matter, while the lower part of the gut contained liquid yellow feculent matter. I do not know to what extent the presence of tape-worm in grouse may be consistent with comparative health, and have never myself examined healthy birds for it, but it is well known that all wild animals are liable to be infested with entozoa.

"In the winter of 1846 immense numbers of the razor-billed auk (*Alca torda*) were thrown up dead on the shores of the Firth of Forth. In all the specimens I examined the intestines contained tape-worm and other entozoa, but so familiar was I with these parasites in marine fishes and other animals, that I attributed the auk mortality at the time to the severity of the weather; but certainly neither before nor since have I seen so many of these birds cast on the shore, though there have been many more severe winters."

A STRONG ADHESIVE PASTE.—According to Fr. Sieburger, an excellent paste may be prepared as follows. Four parts, by weight, of glue are soaked for several hours in fifteen parts of water, and then slowly warmed until a perfectly clear solution is formed. This solution is then diluted with sixty-five parts boiling water and thoroughly stirred. In the mean time thirty parts of starch are stirred into two hundred parts of cold water, so as to form a thin, milky liquid, free from lumps. Into this is poured the solution of glue, stirring continually and heating. When cold, ten drops of carbolic acid are added. The paste made in this way is said to possess extraordinary adhesive power, joining leather, paper, pasteboard, etc. By keeping it in closed vessels, so that the water cannot evaporate, it may be preserved for years. Where no great strength is desired, ordinary flour or starch paste is used, a little carbolic acid being added to prevent souring.—*Journal of Applied Chemistry*.

WATER OF ALL FLOWERS.—An ancient formulary of the seventeenth century has this prescription which was to produce a "Water of all Flowers" (*Aqua Florum Omnium*). The process adopted is remarkable for its simplicity and logical accuracy:

"Send a cow into a meadow full of flowers; when she has eaten all the flowers, gather the dung, distil it, and you have water of all flowers."—*Med. and Surg. Reporter*.

SMALLPOX AND VACCINATION.—An official statistical report of the cases of smallpox occurring in the German Empire during the years 1860-71 shows that of 232,824 patients 28,539 died. The condition as to vaccination is stated in 208,793 cases: 27,793 were not vaccinated, and of these 8894, or 32 per cent., died; 181,000 were vaccinated, of whom 17,260, or 9.5 per cent., died; and 6015 were revaccinated, among whom the deaths were 445, or 7.4 per cent.

LUNACY IN MADRAS.—A report on the working of lunatic-asylums in the Madras Presidency has just been submitted to the Right Hon. the Governor in Council. Among the most interesting of its contents is the section on the cause of lunacy. Of the hundred and fifty-three admissions during 1871-72 into the Madras and Vizagapatam asylums, the probable causes of the disease were ascertained in forty-nine cases, and unknown in one hundred and four. Of the former, twelve were attributed to moral and thirty-seven to physical agencies, — “an experience somewhat at variance with results in asylums in other parts of the world.” The abuse of narcotic drugs in Bengal caused one hundred and seventy-two out of a total of four hundred admissions, or in the ratio of 43 per cent.; whereas in Madras 7.18 per cent. are ascribed to narcotics, proving that ganjah, bhang, and opium are much more frequently consumed in the north than in the south of India.

ENRICUS CORDUS, who died A.D. 1535, doubtless told his own experience, as well as that of his apostolic succession, in the healing art:

“Tres medicus facies habet: unam quando ragatur,
Angelicam; mox est, cum juvat, ipse Deus.
Post ubi curato, poscit sua præmia, morbo,
Horridus apparat, terribilisque Sathan.”

(“Three faces wears the doctor: when first sought,
An angel’s—and a God’s, the cure half wrought;
But when, that cure complete, he seeks his fee,
The devil then looks less terrible than he.”)

Pope sang in the same strain, although he was not one of the brotherhood:

“God and the doctor we alike adore,
But only when in danger, not before;
The danger o’er, both are alike requited,
God is forgotten, and the doctor slighted.”

Dr. D. Clark, Canada Lancet.

A DILEMMA FOR TEETOTALLERS.—We should like to ask the members of the legislature if they are prepared to continue the use of bread as an article of diet, in the face of the following fact, given in the *Medical Press and Circular*:

In the *Chemical News* for May 30, Mr. Bolus says that he has detected a small percentage of alcohol in six samples of new bread purchased at different shops in London. He says, “It is possible that the amount of alcohol contained in bread is too small to be of any dietetic importance, but it may perhaps be worth while to notice that forty two-pound loaves are about equal in alcoholic strength to an ordinary bottle of port.”—*Boston Medical and Surgical Journal*.

SOME time ago a Cork gentleman sold some fox-hounds to an English master of hounds. When they arrived at the kennel they were refused, as not being in accordance with their description. They were then sold by auction and purchased by a London dealer in connection with the provision-trade. An action was brought last week at the Liverpool Assizes to recover their value, and one of the learned counsel remarked that they had been made into sausages. They were described as being “lame, mangy, old, and unbroken.”

so perhaps it is as well that we knew nothing about it at the time.—*London Lancet*, Sept. 6, 1873.

PRESERVING CHARRED PAPERS.—Mr. E. H. Hoskins, of Lowell, Massachusetts, has suggested a very useful and practical way of preserving and giving toughness and flexibility to charred paper, which has proved to be of much importance in the identification and copying of valuable documents charred by conflagration, such as the recent Boston and Chicago calamities. We have seen specimens of charred papers and bank-notes, thus treated, that can be handled with impunity. The printing upon the charred bank-notes can be readily discerned. The preserving process consists, we believe, in pouring collodion upon the surface of the charred paper. The collodion forms a thin transparent film, dries in a few minutes, when the process is complete.—*Scientific American*.

COLLODION IN HORTICULTURE.—The *Gazette des Campagnes* recommends dipping the end of plant-slips in collodion before setting them out. The collodion should contain twice as much of cotton as the ordinary material used in photography. Let the first coat dry, and then dip again. After planting the slip, the development of the roots will take place very promptly. This method is said to be particularly efficacious with woody slips, geraniums, fuchsias, and similar plants.—*Boston Journal of Chemistry*.

DOCTORS ON A STRIKE.—The *Gazette Hebdomadaire* mentions a strike of medical practitioners of the Canton of Aargau, Switzerland, on account of the miserably small fees allowed them for visiting the poor. It appears that a physician is entitled to about fifteen cents for visits at a distance of nearly a mile.—*New York Medical Journal*.

MISS DR. FRANCES A. RUTHERFORD has been appointed Vice-President of the Michigan State Medical Society. Miss Rutherford is the happy possessor of a Philadelphia degree.—*London Lancet*, Sept. 6, 1873.

CALOMEL FOR PILES.—Calomel applied once or twice a day to tumid and tender piles rarely fails to cure them in a few days.—*Western Lancet*.

THIRTY-SEVEN ladies are said to have matriculated already in the Medical Department of the Michigan University.

COST OF AN EPIDEMIC.—The *London Medical Record*, April 16, 1873, states that the late smallpox epidemic cost Dublin at least £35,000.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 21, 1873, TO OCTOBER 27, 1873, INCLUSIVE.

GIRARD, A. C., ASSISTANT-SURGEON.—Assigned to duty at Yorkville, South Carolina. S. O. 183, Department of the South, October 20, 1873.

MATTHEWS, W., ASSISTANT-SURGEON.—To report in person at these Headquarters for assignment. S. O. 206, Department of the East, October 22, 1873.

BYRNE, C. B., ASSISTANT-SURGEON.—Assigned to temporary duty at Wiltet's Point, New York Harbor. S. O. 210, A. G. O., October 23, 1873.

SATURDAY, NOVEMBER 8, 1873.

ORIGINAL COMMUNICATIONS.

THE TEMPERATURE OF THE SEXES; AN INDICATION OF DEVELOPMENT.

BY JOHN STOCKTON-HOUGH, M.D.

SINCE Aristotle declared that man had more warmth than woman, we have had recorded any number of assertions to the contrary, and several proofs corroborative; and yet, as late as 1864, we see the Greek philosopher flatly contradicted by a clever, scholarly naturalist:* so we find some decidedly in favor of one view, others of the opposite opinion, and still others in doubt.

Though we had full confidence in Aristotle's theory and the corroborative evidence of recent skilful observers, yet we felt anxious to test the matter, and the very satisfactory result shown in the accompanying table fully sustains the Aristotelian theory.

Aristotle held that moderation in secretion favors longevity: "this," he says, "is why females live longer than males."† "Males ought by nature to be longer-lived than females, since they have more warmth."‡ Again, "The male must necessarily be warmer than the female."§

After discussing the different qualities of the blood, and the various parts to which it is supplied, he says, "Hence the upper|| and lower parts, the right¶ and left sides, the male and female, manifest their differences" [in temperature].**

Aristotle arrived at these conclusions (deductions) from *philosophical and analogical reasoning*, not having any delicate instrument like the thermometer, while modern investigators rely upon the thermometer almost entirely. His detailed observations and philosophical deductions are without an equal in the history of science since his time, and we are not surprised that Cuvier says that "One sees that on certain points of detail he is a better observer than the majority of his successors."

Dr. John Davy, F.R.S.,†† the great anatomical

* George Henry Lewes: "Aristotle: A Chapter from the History of Science," etc., etc., Lond., 1864, p. 268 (note): "Modern investigations show that the average of life is slightly in favor of women, and that their temperature also is slightly superior to that of men." The greater longevity of women than of men is forcibly shown in the author's paper on "Longevity or the Relative Viability of the Sexes; particularly with regard to the relative liability to the inheritance of certain transmissible diseases, considered in relation to the selection of life-insurance risks, with a view of exhibiting the unjustness of the practice of charging higher rates for women," etc., etc.,—*New York Medical Record*, June 16 and July 15, 1873, pp. 297-303, 403-405.

† Confirmed in the author's article on "The Relative Viability of the Sexes," *New York Medical Record*, June 16 and July 15, 1873.

§ De Generat. Animal., B. iv. ch. i.

|| Aristotle (De Partibus, B. ii. ch. vii.) says, "The brain is the coldest part of the body." Compare Dr. John Davy (Res. Phys. and Anat., Lond., 1839, 8vo, vol. i. p. 157), where he says, "From the results of some observations already detailed, it would appear that the temperature of the brain is not quite so high as that of the rectum." In several experiments on sheep the brain was from .5° to 2° Fahr. lower than the rectum.

¶ Aristotle (De Partibus, B. iii. ch. iv.; also, De Generat. Animal., B. iv. ch. i.) maintained that the right side is warmer and nobler than the left. See further in the writer's paper on "The Developmental and Functional Superiority of the Right Side, and the Greater Frequency of Disease, Deformity, and Defect in the Left" (not yet published). Compare also Tamburini (La Nuova Lig. Med., March 10, 1873) on the "Functional Superiority of the Left Hemisphere" (or the brain). It is important, therefore, that the temperature should be taken on the same side.

** De Partibus, B. ii. ch. ii., Partes Similares; Lewes's Aristotle, p. 298.

†† Report of the Brit. Assoc. for the Adv. of Sci., 1864, p. 121.

and physiological investigator, has shown by carefully conducted and frequently repeated experiments that the temperature of men and of the males of some of the inferior animals is superior to that of their females.

In the human race the average is as

10.58 for males is to 10.13 for females:

from elaborate experiments,—

for males, 99° to 99½° —average, 99¼°

for females, 97¾° to 98° —average, 97.875°

Difference in favor of males, 1.375°

In the common fowl a well-marked difference was discovered in temperature between the male and female. Of six fowls the proportion was 108.33° Fahr. for the male, and 107.79° Fahr. for the female, giving a difference of .54° Fahr. in favor of the male. The maximum for the male was 108.5°, for the female 108°.

"In a large number of instances, in which comparative trials were made with much care, he found the temperature of the woman a little lower than that of the man."††

The following table of experiments on children fully corroborates this sexual differentiation:

Table showing the temperature of twenty-seven children, taken by the writer in the Obstetrical Wards of the Philadelphia Hospital, September 27, 1872, with discriminations of age and sex. (Taken in the axilla, at noon of the same day.)

No.	Ages.	Temperature in Degrees of Fahrenheit.		Average for the various periods (both sexes).

†† Report of the Brit. Assoc. for the Adv. of Sci., 1864, p. 121.

‡ The writer is indebted to the courtesy of Drs. Parry, Girvin, Duer, Ingham, Parish, and Potter, physicians to the hospital, for the privilege of making these observations.

The temperature of boys, ranged from 97.2° to 99.4° ; difference, 2.2° .
girls " " 97.6° to 99.2° ; difference, 1.6° .

The average temperature of
5 children aged 20 to 36 hours, was 99.14° Fahr.;
6 children aged 3 to 10 days, was 98.53° Fahr.;
7 children aged 2 to 9 weeks, was 98.17° Fahr.;
9 children aged 3 to 44 months, was 98.09° Fahr.;
Total, 27 children, average temperature, 98.37° Fahr.

Dr. John Davy, F.R.S.,* also found the variation in temperature to be greater among males than among females,† as will be seen by the following:

Three men,
from 99° to $99\frac{1}{2}^{\circ}$, mean $99\frac{1}{4}^{\circ}$; variation $\frac{1}{2}^{\circ}$.
Three women,
from $97\frac{3}{4}^{\circ}$ to 98° , mean 97.875° ; variation $\frac{1}{4}^{\circ}$.
Difference in favor of men, 1.375° .

Women, therefore, have a lower temperature than men, and it is undisputed that they have a more frequent pulse than men. Valleix‡ has shown that the pulse of infants is subject to the following law, viz.:

In new-born children the pulse is less frequent than at the age of six months; the mean frequency while sleeping was 87; but, sleep itself being a cause of diminished frequency of the pulse, it is necessary to select a somewhat higher figure as that of the normal pulse. Everything warrants the supposition that this varies in frequency from 90 to 100.

I have shown in my tabulated observations that the temperature of new-born children is higher than at the age of six months,—indeed, that it gradually declines from the hour of birth to a certain age; and, as this temperature is lower than that of adults, there must be a time when it begins to rise, probably at the approach of puberty, or even earlier.

My table shows a gradual decline in temperature for each of the periods, though they were so short and near together.

The boys had a temperature of 98.44° , and the girls 98.30° , giving a difference in favor of the males of $.14^{\circ}$.

Children, therefore, have a higher temperature and a less frequent pulse at a few hours after birth than they have at any period afterwards, up to forty-four months (the highest age taken). They have also a lower temperature and a more frequent pulse than adults of the same sex. In these particulars, as, indeed, in all others of a developmental character, women stand between children and men.

It would appear to be a law, in healthy persons at least, that wherever we find a frequent pulse we have a lower temperature, indicating a relatively lower development, and *vice versa*.

Dr. W. F. Edwards found the temperature of the young of various animals to be from 1° to 3° Fahr. and from 2° to 5° Cent. inferior to that of their parents. Among the animals under observation were

the following: pups, rats, rabbits, guinea-pigs, star-hawk, magpie, thrush, starling, etc., etc.

The following figures are the result of his experiments on man:

	MEAN.	RANGE.	VARIATION.
Twenty adults,	97°	96° to 99°	3° Fahr.
Ten infants,	94.5	93.5 to 96	2.5

He concludes that "man is therefore proved to be subjected to the same law here as animals having warm blood in general, the young of which, so far as they have been examined, and, we may presume, universally, are inferior in temperature to their parents."§

"Dr. John Davy|| found that the temperature of a lamb was a degree higher than that of its mother; and in five new-born children the heat was about half a degree higher than that of the mother, and rose half a degree more in the first twelve hours after birth."¶

This method of comparison is subject to several sources of fallacy, so far as our object is concerned; for the mother's temperature** is manifestly not the same immediately after the birth of her child as that of a healthy vigorous woman who had not had any severe physical disturbance, such as child-birth undoubtedly is; and the mere fact of lying in bed for several consecutive hours is sufficient to render the comparison useless for our purpose. We want the average temperature of a large number of healthy children in lots of the same age, same sex, and same physical and social position, as compared with an equal number of adults taken in the same manner with reference to age, sex, condition, etc. When we have all the conditions fulfilled, we will find the same results as M. Edwards, viz.: That young persons have a lower temperature and a higher pulse than adults, until we reach extreme old age, when the second childhood returns, with its physical characteristics,—a lower temperature, a higher pulse, etc.

M. Roger†† made a very extensive series of experiments on the temperature of young children in health and in disease. According to Dunglison,‡‡ he found "in nine examinations, from one to twenty minutes after birth, the temperature observed in the axilla was from 99.95° to 95.45° . Immediately after birth it was the highest, but quickly fell to near the lowest point stated above. By the next day, however, it was entirely, or nearly, what it was before. The rapidity of the pulse and respiration appeared to have no certain relation to the temperature. In thirty-three infants, from one to seven days old, the most frequent temperature was 98.6° ; the average 98.75° ; the maximum, one case, 102.2° ; the minimum, also one case, 96.80° . All the infants were healthy. The frequency of respiration had no evident or constant relation to the temperature.

† Of the stature of the human race Geoffroy St.-Hilaire says, "The size of women is less variable than that of men;" and this would probably be found true of other physical comparisons.

‡ Mémoires de la Société Médicale d'Observation de Paris, tome ii., Paris, 1844. Review in Med.-Chir. Rev., April, 1845, p. 390; compare also Mr. Gorham (Med. Gazette), M. Trousseau, and M. Billard.

A few of the infants were of a weakly habit; their average temperature was 97.70° ; the others were strong, and their average temperature 99.534° . The age, at this period, had no influence on the temperature, nor had the sex, state of sleeping or waking, nor the period after sucking.

"In twenty-four children, chiefly boys, from four months to fourteen years old, the most frequent temperature was above 98.6° ; the average 98.978° ; the minimum 98.15° ; the maximum 99.95° . The average of those six years old or under was 98.798° ; of those above six years, 99.158° . The average number of pulsations in the minute was, in those under six years, 102; above that age, 77: *yet the temperature of the latter was higher than that of the former and of younger infants.* There was no evident relation between the temperature and frequency of respiration; nor, in a few examinations, was the temperature affected in a regular way by active exercise for a short time, or by the stage of digestion; though 'Gierse* found that the temperature beneath his tongue was 98.78° before, and 99.5° after, an early dinner.'"

"Dr. G. C. Holland† found that the mean temperature of forty infants exceeded that of the same number of adults by $1\frac{3}{4}^{\circ}$: twelve of the children had a temperature of from 100° to $103\frac{1}{4}^{\circ}$."

M. Edwards,‡ on the other hand, found that in the warm-blooded animals the faculty of producing heat is less the nearer to birth, and that, in many cases, as soon as the young dropped from the mother the temperature fell to within a degree or two of that of the circumambient air; and he moreover affirms that the faculty of producing heat is at its minimum at birth and increases successively to the adult age. His trials on children at the large Hôpital des Enfants of Paris, and on the aged at Bicêtre, showed that the temperature of infants one or two days old was from 93° to 95° Fahrenheit; of the sexagenarian, from 95° to 97° ; of the octogenarian, 94° to 95° ; and that, as a general rule, it varied according to age.§

M. Edwards further states that warm-blooded animals, born with the eyes closed, resemble the cold-blooded animal; the latter, or those born with the eyes open, the warm-blooded. He actually found the temperature of a seven months' child, two or three hours after birth, was only 89.6° Fahr. He suggests that that of a child born in the fifth or sixth month, before the membrana pupillaris disappears from the pupil, ought to be much lower. This state of the eyes must be considered as indicative of the immature stage in the development of the animal. It would be interesting, as a further confirmation of this law, to observe the temperature and pulse in the young of marsupial animals.

Under what circumstances Dr. Holland could have found such a uniformly high temperature as 100° to $103\frac{1}{4}^{\circ}$ in children, I am entirely at a loss to comprehend or imagine. There is, without doubt, some source of fallacy in these observations, as they are at

variance with the results of all similar experiments, and opposed to all the theories hitherto propounded.

It is important to know that the sanguine temperament indicates the highest physical development, and that persons having this temperament have a larger proportion of red corpuscles and solid constituents in their blood, and a higher temperature, than persons of any other temperament, particularly the lymphatic, which latter, according to a French physiologist, accompanies physical degeneracy of the race. It is, therefore, quite possible that a woman with a sanguine temperament may have a higher temperature than a man with a lymphatic temperament. The sanguine temperament is, I believe, more frequent among men, and the lymphatic more frequent among women.

The following is a summary of conclusions and deductions arrived at from a careful study of this subject:

1. That males have, as a rule, from the beginning to the end of life, a higher temperature, and a less frequent pulsation of the heart, than females, varying, nevertheless, according to temperament, constitution, age, and condition of health.

2. That children have a higher temperature at birth, and for a short time subsequently, which, though slightly lower than that of an adult, nevertheless slowly and gradually declines to a certain point until about the sixth year of age is reached, after which it gradually increases until developmental maturity is reached, when it gradually and slowly declines again as old age (second childhood) advances.

The pulsation of the heart follows just the opposite course, being most frequent when the temperature is lowest, and least frequent when it is highest.

3. That males appear to have a greater variation in temperature than females, thus agreeing with their greater variation in stature and many other peculiarities.

4. From all of which we conclude that the woman approaches more to her condition as a child than the man does, and is consequently less highly developed. The male is a secondary evolution from the female.||

2003 WALNUT STREET, PHILA., September 29, 1873.

IS THE PRESENCE OF THE HYMEN A PROOF OF VIRGINITY?

BY CHARLES W. BROWN, M.D.

I PRESENT the following case to your numerous readers as a rare one, and also to show the value of an unruptured hymen as proof that rape has not occurred:

|| See further on this theory of development in the author's papers on "The Relative Viability of the Sexes," etc., etc., New York Medical Record, June 16 and July 15, 1873, pp. 9; also, "Longevity and other Biostatic Peculiarities of the Jewish Race," N. Y. Med. Record, May 15, 1873, pp. 241-5; also, "The Laws of Transmission of Resemblance from Parents to their Children," New York Medical Record, August 15, September 15, October 15, and November 15, 1873, pp. 15; also, "Statistics relating to Births, Deaths, Marriages, and Movement of Population in Philadelphia for the Eleven Years ending 1871," Penn Monthly, September, 1873, and Papers of Social Science Association of Philadelphia, 1874, pp. 24; also, "The Physical Aspects of Primogeniture," New York Medical Record, December 15, 1873; also, "Effect of Nationality of Parents on Fecundity and Proportion of Sexes in Births," also, "Observations on the Relation between Development and a certain Abnormal Condition of the Flowers of Zea Mays;" also, "The Proximate Cause of Evolution" (not published).

§ Dunglison, Physiology, vol. i. p. 600.

October 10, 1873, I was called to see Mrs. W., aged 26; found her pregnant, full time, and in early stage of labor. She was very much frightened, and told me her child could not be born, as there was "no opening, and never had been." Upon examination, I found the hymen intact, and quite firm and rigid. Towards the lower part of the membrane I found a small aperture less than one-quarter inch in diameter. The parts were excessively tender, and it was with difficulty that I could introduce the tip of my little finger. In this way I commenced the dilating process by gentle but steady pressure until I could introduce the tip of the first finger. By keeping up this process for two hours I could with difficulty introduce the first and second fingers. I found the os had not dilated any, and was rigid. Gave patient a full opiate, and saw her again in three hours; found the os in a more dilatable condition, and pains increasing. The patient being a slender small woman, the pains did not increase as they should; but after administering quinia, alcoholic stimulants, etc., the pains came more regularly and with more force. At the end of ten hours the head was resting in the lower strait, and the pains did no good; the cranium of the child being hard and unyielding, the pains were growing weaker. I then gave ergot, with but very little effect. In two hours more I applied the forceps, and in a short time she was delivered of a large healthy female child; and in the course of half an hour the placenta was delivered, patient being in a very comfortable condition. She recovered without any unfavorable symptoms, but without any lacteal secretion. About eighteen months since, she had an abortion at about the second month; she was treated by Dr. E.; the fœtus and membranes passed off through the small opening in the hymen, and she made a good recovery.

I think I have never read of a case becoming twice pregnant with the hymen intact.

MANSFIELD, TIOGA CO., PA.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY OF PENNSYLVANIA.

SERVICE OF DR. H. C. WOOD,

Clinical Lecturer on Diseases of the Nervous System.

Reported by Dr. LOUIS STARR.

EPILEPSY ARRESTED BY STOPPING AURA—SIMULATED NOCTURNAL EPILEPSY—EPILEPSY WITHOUT LOSS OF CONSCIOUSNESS—EPILEPTIC DELIRIUM.

IT is difficult to give a correct definition of epilepsy, as different types of it are met with: it will be better, therefore, to lay before you a typical sketch of the disease, and then show how it varies. The affection is made up of a series of paroxysms which occur at irregular intervals. Each attack begins with an *aura* starting in some distant part of the body, as in one of the fingers or in the foot, and extending upward: when it reaches the head, a loud shriek is given, and the sufferer falls unconscious; as he falls, the face becomes deadly *pale*, and the body rigid, being in a state of tonic spasm. This condition lasts but a few seconds, and is hence often overlooked. The convulsion next becomes clonic,—that is, the muscles are forcibly contracted and

relaxed in rapid succession; the face is now turgid and distorted, the head, trunk, and limbs are jerked about with violence, the tongue is protruded and wounded by the teeth, and blood-stained saliva runs from the mouth. The clonic spasm rarely continues over six minutes, and usually not more than three or four. Paroxysms of such character and duration may either be single or a number of them may occur in quick succession; when they are over, there is total unconsciousness of what has happened, and very often deep sleep; on waking from this the attack is ended, to return again after a longer or shorter time. At first the mind is clear during the intervals, but grows less so as the disease advances. These points are well illustrated by the case before you. The patient is thirty years of age, a bar-tender by occupation, and for the past six years has been intemperate and excessively addicted to venery. Although much exposed, he has never had any venereal disease. Three or four years ago he began to have epileptic attacks coming on during sleep: these occurred frequently, sometimes once every night, at other times only once in two or three weeks, and were often accompanied by seminal emissions. At present, according to his own statement, he copulates from once to four times daily, and drinks in the same proportion; he has never had an attack during coition, but on several occasions some hours after the act. The paroxysms begin with pain in the stomach, and a sensation in the ring-finger of the left hand like that produced by the faradaic current: this quickly passes over the whole hand, and then up the arm, which is moved about violently during the passage; when the aura reaches the head he becomes unconscious. The duration of each fit is short, and as soon as it is over he falls into a heavy sleep, from which he wakes with a severe headache. The attacks can be stopped by grasping the left wrist firmly or by rubbing the left hand when the aura is first felt: this he always does in the daytime; at night, however, he rarely wakes up soon enough, for after the aura has passed the wrist it cannot be arrested. On this account the great majority of the paroxysms have taken place at night.

The word *aura* means air, and is used because the sensation which precedes the epileptic seizure sometimes resembles that produced by a draught of cold air running up from the part first affected towards the cerebral centres. There are three forms of aura: the sensory, the molar, and the stomachic. The first, so called from its being manifested by some abnormal sensation, as heat, cold, or formication, is very rapid in its course. The feeling of a cold breath creeping through the system, from which the term *aura* is derived, belongs to this class, but is hardly ever met with. The second variety of aura is distinguished by either convulsive movements or paralysis, starting in distal portions of the body and extending upward; while the stomachic form consists of pain or other unusual sensation beginning at the pit of the stomach, exceedingly swift in its transmission, and most frequently observed in females. If the aura can be checked in its course, the paroxysm is prevented; at the same time, it must be remembered that it is often far too quick in its passage for this to be done, and that there are many cases in which aura does not exist. In the man before you the aura belongs to the sensory class, and is probably of centric origin. This question of origin, whether central or peripheral, is a curious one, and one upon which proper treatment depends: care should therefore be taken to investigate it, though such investigations are by no means always successful.

Epilepsy may be due to hereditary tendency: so universally is this accepted that Frank reports that it was an old Scotch custom to castrate all epileptics, in order that the race might die out. Nervous diseases—for

example, hysteria, epilepsy, and insanity—are very closely related, and often alternate in successive generations. Other causes are acute diseases, exposure to the sun, and organic disease of the brain, or it may arise spontaneously, apparently without cause. In this patient it is evidently due to excessive vena. The first indication in treatment is to remove the cause, when it can be determined: until this is done, little benefit may be expected from medicines. In bromide of potassium we have a valuable remedy: its mode of operation is to lessen reflex actions and the excitability of the nerve-centres; but in order to accomplish this it must be given in full doses (3j t. d.) and increased until some effect is produced,—that is, until the blood has, as it were, become super-saturated with the salt. Notice should be taken of the fact that bromide of potassium is useful in proportion as the paroxysms are frequent, violent, and fully developed, being much less so in the various modifications of the disease. Next to the bromide in point of utility may be mentioned belladonna and nitrate of silver,—the former being given in sufficiently large doses to produce slight dryness of the throat, and the latter in doses of one-fourth to one-half a grain, continued for some time, always bearing in mind the danger of producing discoloration of the skin: this may be avoided by discontinuing it for several weeks after it has been taken for six or eight weeks, especially if iodide of potassium is used in the interval.

The man before you has his attacks in the night, but only because in the daytime he always arrests the paroxysm. There is, however, a form of epilepsy—"night-epilepsy" so called—in which the paroxysms occur only at night: they may be violent, when they are easily recognized; they may be so insidious as not to be suspected by the sufferer, and only to be discovered by the physician after the most careful search. When, however, in an adult, complaints are made of a feeling of apparently causeless malaise, with confusion of thought and headache on getting up in the morning, always be on your guard, and if the tongue is bitten and the urine voided in bed at night an almost certain diagnosis of "night-epilepsy" can be made. Of course the diagnosis of epilepsy should not be given hastily, as the prognosis is so frightful; yet, though you hold your peace, never be deceived in these cases, especially since very frequently a full dose of bromide at bedtime every night will arrest the disorder.

Wetting the bed at night is one of the most characteristic symptoms of this form of epilepsy, and its presence or absence should influence very greatly your decision. Not long since I was consulted by a distinguished practitioner, who feared that he was suffering from this affection, but in whom I was able to make a more favorable prognosis, which so far has been verified. Some years before, he had broken down from overwork, and, although he had in great measure recovered, had never regained his normal mental vigor and power of work. He had noticed for some time that his tongue was bitten on getting up in the morning, and he was partially conscious of the fact, or had the idea, that the injury occurred just at waking. He had never wetted the bed, had never suffered from any mental disturbance or malaise after the biting of the tongue, had never suffered from "petit mal" or any form of diurnal epilepsy. I therefore told him I did not believe he had nocturnal epilepsy. Still, the fact of the bitten tongue remained. Knowing that he had suffered at the time of his break-down a slight paralytic stroke, I suggested that perhaps one side of the tongue had remained less sensitive than the other, and that, lacking this guide to its movements, it sometimes got between the teeth and was bitten, especially in the first movements of waking, when the senses are all benumbed with sleep. Examination showed this to be the case; and he also stated that the

injury was always on one side of the tongue,—namely, that in which the sensation was impaired. Now, if these two points had escaped observation, much doubt might have been felt as to the nature of the case.

In *petit mal*—the second variety of the disease—there are no convulsions, and the loss of consciousness is of such short duration that the muscles remain contracted and there is no fall.

I do not propose to say much to-day about this *petit mal*, but merely to allude to a rare and very serious form of it, in which a paroxysm of delirious fury replaces the usual momentary simple loss of consciousness. This delirium is furious in character, very often homicidal. Generally there is a marked destructive tendency, or the patient fights those around him, under the delusion that he himself is being attacked. The celebrated alienist Dr. Gray was some time since sitting at a table with a lawyer who had suffered from *petit mal*, when the latter attacked him with a knife, intent upon his life. The case whose history follows presents itself to us for diagnosis. The point to be determined is whether the man has or has not had a paroxysm of epileptic delirium.

Joshua H. C., æt. 42, white, has always enjoyed good health. About three weeks ago, having been exposed to much cold and wet in his occupation (that of a car-driver), he took a severe cold, which kept him at home for three or four days. At this time there were no epileptic symptoms. After this he felt well until last Sunday morning, October 26, when he went out to walk, very thinly dressed, although the day was quite chilly. On returning to his home he had a severe chill, and complained of dimness of vision, lasting about three-quarters of an hour, with frontal headache and vomiting. His friends say that after this he was wildly delirious, doing peculiar things, seizing and hugging his wife, rushing around the room, yelling, etc., etc., but not offering violence to any person, and showing no destructive tendencies whatever. It should be mentioned that he has always been nervous and excitable, and that the night before this attack he had had a domestic quarrel.

Under cupping to the back of the neck, the man recovered his reason in about twenty-four hours.

In many respects this case is obscure. At first sight it resembles epilepsy. But there is no history of wetting the bed, or of other indications of night-epilepsy,—of momentary loss of consciousness, or other indication of *petit mal*; and the delirium was unlike the usual form of epileptic furor in that it was not directed to the destruction of any object, either animate or inanimate. Cantharides, Indian hemp, or atropia, when taken in sufficient doses, might produce similar symptoms; but this man has not taken them. It cannot have been meningitis, for there was no fever; nor was the attack malarial,—although I have seen pernicious fever with very similar symptoms,—for the chill has not returned; nor is brain-tumor the cause, since, although sudden symptoms may come from such cause, yet there are generally apoplectic symptoms, and indications of paralysis exist in a greater or less degree somewhere. Moreover, the patient has not had any marked headache. I think the case, being none of these, is probably *mania transitoria*, which often occurs after chronic diseases, great anxiety, and the like, and which in many respects is closely allied to hysteria. In the case now before us it was probably induced by exposure to cold and by the excitement of a domestic quarrel.

In the third and last variety of epilepsy there is no loss of consciousness. This form is very rare, and even the possibility of its occurrence has been denied by many authorities, who hold that unconsciousness is the only symptom of epilepsy that is never absent. The following history shows that this form may be met with. Thomas —, æt. 20, began to have epileptic fits nine years ago.

The paroxysms from the outset have been frequent, from one or two every week to three or four daily. They are always preceded by a well-marked aura, originating in the feet and passing upward; when it reaches the arms the convulsion begins. This affects both arms, the muscles of the upper part of the back, and those of the neck. During the spasm the pupils are widely dilated, the face is congested and disfigured, the head is drawn to the left, and the arms are lifted above the head and jerked wildly about. The attack lasts about thirty seconds; there is no loss of consciousness, and he does not fall. He had an attack at one of his visits to the dispensary; so that the truth of his statement as to the loss of consciousness can be fully verified.

From March 10 to July 10 the treatment adopted was, first, large doses of bromide of potassium, then belladonna with nitrate of silver, and, finally, bromide of sodium; and, although the paroxysms appeared at times to diminish in frequency, no great improvement was brought about. Since July 4 he has not been seen, and most likely he has applied for aid elsewhere; though it is hardly possible that anything can be done to give him permanent relief.

This case, I think, must be considered as of the nature of epilepsy, from its commencing with aura, its paroxysmal nature, and its intractableness. If you use the term *cerebral epilepsy* for that form of petit mal in which consciousness is not lost, you may speak of this form, in which consciousness is preserved but convulsions occur, as *spinal epilepsy*.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. T. G. MORTON, SEPTEMBER, 1873.

Reported by DR. D. DAVIDSON.

GUNSHOT-WOUND INVOLVING THE STOMACH.

CASE I.—*Post-mortem.*—This specimen was removed from a man aged 21, brought to the hospital in September. A few hours before admission he was struck by a small ball, which entered an inch below the arch of the ribs, in front and on the left side. Considerable blood was vomited immediately after the injury; intense pain and prostration were prominent symptoms; the pulse was feeble and quick. Magendie's solution in fifteen-minim doses was freely given by the skin. The following day his condition was the same, except the advent of tympanites; and large doses of morphia were constantly given, to relieve pain. On the third day there was marked peritonitis, and death occurred on the fourth day. On examination we find that the bullet pierced the abdominal walls about three inches below the ensiform cartilage and one inch on the left of the median line, passed somewhat downwards and to the left side, cutting through the border of the left lobe of the liver; its course was then traced through the anterior and posterior walls of the stomach; passing backwards, the eleventh rib was fractured, and the ball was found imbedded in the quadrate muscle.

The abdominal viscera are more or less agglutinated together by recent lymph.

In a case like this, the treatment consists simply in giving powerful opiates and supporting the patient; there is never any use in probing for the ball in wounds of the viscera, for it is not the presence of the ball, but the injury the ball has inflicted in its course, that does the damage.

STRICTURE OF THE ŒSOPHAGUS.

Case II.—This negro presents himself for examination; he is only 50 years of age, although he looks much older; we see that he has suffered severely; he is greatly emaciated. He states that his health was per-

fect until two or three months since, when he experienced a constriction or choking sensation in swallowing; he has rapidly grown worse, and now is unable to swallow any kind of food; even a few drops of water give intense suffering. These symptoms indicate a stricture, and may have been produced by the lodgment of a foreign body in the œsophagus; but the patient has no recollection of any such accident. On examination, we find no enlargement of the throat glands of the neck; there is no arterial tumor pressing on the passage: we therefore suspect, from the rapid wasting of the patient, his age, and the quick development of this disease, a growth probably carcinomatous.

In order to ascertain the location of the stricture, I introduce the ordinary stomach-tube, and find about eight inches from the mouth an obstruction so obstinate and sensitive that I am unable to carry the instrument beyond it into the stomach. There is unquestionably a stricture, which is probably cancerous. Since we cannot dilate the constriction, we advise the patient to be fed by the rectum with concentrated food, and three times a day we shall give him ten grains of the iodide of potassium by injection. Gastrotomy might be performed, but the patient is too feeble for us to recommend such an operation.

[The above patient died in September, and on a post-mortem examination a dense scirrhus growth was found encircling the œsophagus midway between the stomach and the pharynx. Dr. Richardson, the pathologist, reports that "the tumor is seated between the bifurcation of the bronchi and the œsophagus (the latter of which it surrounds and constricts), 'cries' under the knife when cut, and yields on scraping an abundant milky juice. Under the microscope this juice exhibits an immense variety of oval, caudate, spindle-shaped, and multangular cells, many of them with two or three large nuclei, and a few showing the characteristics of *mother-cells*. Thin sections from the neighborhood of the incision display a rather firm stroma, with moderately thick trabeculae, in the meshes of which the lawlessly-growing cells are arranged in groups, without any intercellular substance between the individual elements. The specimen is, therefore, one of *scirrhus cancer*."]]

TRANSLATIONS.

ENCEPHALIC SOFTENING IN THE NEW-BORN.

By M. J. PARROT. Translated from the *Archives de Physiologie* for January, March, and May, 1873.*

By FRANK WOODBURY, M.D.

THE author shows from the bibliography that this subject is comparatively new, very few of those writers who are in the best position to discuss it having referred to it; even these mention it in such an incidental manner as to show that they have failed to clearly separate it from post-mortem change. The article is based upon personal observation of twenty-eight cases occurring in premature births and infants (the oldest of which was thirty-six days): these are quoted under the different subdivisions of the special pathology of the subject, which are taken up consecutively, as follows:

Pathological Anatomy.—In the *normal* condition the dura mater of the new-born adheres strongly to the

* The article is here condensed, and the description of cases omitted, for which the reader is referred to the original, of which this is an abstract rather than a translation.—F. W.

calvaria and is removed with it. The meninges are easily detached from the convolutions, which are much less clearly defined and have comparatively less depth than in the adult. The brain-substance itself is soft, friable, and in consistency and color resembles freshly-curdled milk slightly tinged with coffee. It is deficient in white nervous substance and neuroglia, but contains a multitude of cells surrounded by protoplasm. This description applies more particularly to the hemispheres, the other portions of the encephalon being in a more advanced stage of development. There is another particularly important point in the structure of the cerebrum: it is the existence, among the elements mentioned, of fatty granules grouped around the cells of neuroglia, where they are sometimes so numerous as to form a true granular body. These are most frequently seen in the corpus callosum and periventricular region of the lateral ventricles. In the normal condition these masses of fatty molecules are always isolated; they are also found in the nerve-tubes before they are fully developed, but not after. The presence of fat, then, in the brain is an indication of its imperfect condition.

The molecules of the brain-substance being so feebly united, we can easily understand that the encephalon yields readily to influences which tend to diminish the cohesion of those particles. These influences are of two kinds: morbid, acting during life, and physical, coming into play only after death.

Post-mortem change is indicated by the odor of sulphuretted hydrogen, by the general softening, and by section, which exhibits numerous grayish opaque spots the size of a pin's head, composed of vibrones. In these cases softening generally is found in the other viscera. These results are more marked when the brain has previously been the seat of disease.

Pathological softening is of two kinds, requiring separate description. The first is the more frequent and clearly defined, but, at least to our knowledge, has not been described by any author (we except M. Virchow). This we will call *multinodal white softening* (*ramollissement blanc à foyers multiples*). It is intimately connected with, and forms the ultimate stage of, fatty degeneration. The fat, when in considerable quantity, is aggregated in white patches and intersperses apparently healthy tissue. These patches contain centres of softening, and exist almost exclusively in the centre of the hemisphere near the lateral ventricles, into which they never penetrate, being separated at least by the lining membrane. Outside of the patches is diffuse interstitial fatty deposit, and the vessels, especially at the periphery, are markedly congested.

The other variety is *red softening*. On making a section of the hemispheres, the cerebral material in their centre, to a greater or less extent, is found to be converted into a reddish-violet pulp interspersed with dark points and tracts which are vessels filled with coagulated blood. The surrounding region is much congested, and sometimes exhibits capillary hemorrhage. Like the preceding lesion, it never invades the lateral ventricles during life. In most of the cases examined there was found a thrombosis of the entire encephalic venous system; the veins being sometimes surrounded by a yellowish exudation, which, infiltrating the arachnoid, formed opacities of variable extent. In this red softening we also find fatty degeneration, which rarely, however, is in such quantity as to produce patches. This, however, might easily occur, as it is simply a question of degree, although it was not met with in any of the detailed cases. Thus the two kinds of softening, although varying in some of their conditions, are identical in their pathology.

The condition of some of the other organs merits attention. The oldest or primary lesions affect the

upper part of the digestive tube. Muguet extends sometimes as far as the gastric mucous membrane, which contains numerous ulcers of very small diameter. The other lesions resulting from this are alterations of the blood and of different viscera. The blood is less abundant than in health, and shows enlargement and disposition to concretion of the globules, not only in the brain, but elsewhere. In the lungs congestion and centres of inflammatory hardening are rare, but emphysema often exists, with fatty infiltration of the alveolar epithelium. The heart shows some fatty change, which also affects the renal tubules. The visceral fatty degeneration differs in degree in different cases, but is always indubitable evidence of impaired nutrition.

Symptomatology.—In twenty-three of the cases we noted occasional signs of brain-trouble, but they were fugitive and showed nothing characteristic. In seven only did it take the form of well-defined convulsions; but whether this was due to the softening remains to be seen. In the mean time we declare that in those patients where the softening was the consequence of fatty patches there was nothing that could give a hint of its existence.

A fact worth noting is that the temperature was not elevated above the normal, even in a case complicated with meningitis. The radial pulse did not exceed 136.

Etiology and Nosogenesis.—The cases were nearly equally divided as regards sex. The oldest was 36 days, and in some the ossific centre in the femur was either absent or smaller than in infants at term. The season of the year exercised little or no influence upon the disease. Digestive troubles were the usual complications; since in nineteen out of twenty-three cases they were the first symptoms, and ceased only with death.

But in order to understand the morbid connection it is indispensable to distinguish the two kinds of softening. We find the white softening, which is the most frequent, constantly among infants suffering from inanition, because this has for its point of departure gastro-intestinal troubles or accompanies anasarca, as a consequence of the native weakness which is the most constant cause of the œdema of the new-born. In a previous paper we proved that inanition engendered fatty change in the brain.*

In seven cases we found red softening, in five of which clots were found obstructing veins of the brain and dura mater, with or without an exudation of leucocytes around the vessels. It is easily seen how the red softening is produced. The occlusion of the veins obstructs the local circulation, causing distention of the capillaries and a transudation of serum; this imbibed by the brain-substance reduces its consistence, to be still further diminished by mixing with blood extravasated by rupture of some of the minute and poorly-nourished vessels. The venous thrombosis is undoubtedly due to an alteration in the blood, because the same condition is found in the kidneys and sometimes in the pulmonary arteries. Following the troubles of digestion and nutrition, the blood loses its serum and becomes thickened; this consistence and the defective impulsion of a feeble heart produce a notable slowing of the circulation. The leucocytes, relatively or absolutely increased, aggregate along the vascular walls, and there form a mass which is a point of departure for thrombosis. In fact, we saw that certain of the venous clots were entirely composed of leucocytes.

Pathology.—In only six of the cases were there unmistakable convulsions, and these were dissimilar. In each of these additional causes were present which might account for the phenomena; such as meningitis, disease of the cerebellum, or renal thrombosis. In one

* Sur la Stéatose viscérale par Inanition chez le Nouveau-né, in Comptes-Rendus de l'Académie des Sciences, 18 Août, 1868.

of the cases the child was evidently an idiot, which we will merely mention here, reserving its discussion for another article, in which cases of idiocy will be considered whose cerebral lesion is connected with that discussed in the present article.

Encephalic softening may exist beyond the point of infancy without losing the characters above shown. It is found in the foetus and in children of several months or even years, in which case its début is difficult to fix, but is probably not far from birth. Some of these cases had a serous effusion distending the lateral ventricles, due to the brain-softening, which was entirely unsuspected during life.

In twenty-three cases the disease remained, so to speak, latent. In reflecting upon the semeiology of this affection, we are forced to the conclusion that the lesions of the cerebral substance proper, however extensive or pronounced they may be, only in an exceptional manner exhibit themselves by appreciable phenomena.

The studies we have just made would be devoid of value to general pathology if we did not in the same connection consider the cerebral softening of different epochs of life, in order to point out their analogies and differences. Why does it occur most frequently at the two extremes of life? What causes concur in the aged and in the new-born?

In senile softening we find a uniform lesion, clearly circumscribed, occupying indifferently the periphery, centres of the hemispheres, or the ganglia, and, when it has existed sufficiently long, establishing a kind of cicatrization and provoking secondary atrophy of the neighboring structures. Very unlike this is the lesion in the new-born: in almost all the cases the disease is limited to the hemisphere proper, affecting symmetrically its medullary centres, only invading the convolutions exceptionally and when the disease is old. The lesion may be diffused or in small but numerous spots. The patient rarely survives long, but even in such cases we do not meet anything resembling the yellow patches or cellular infiltration of senile softening. The altered nerve-substance is gradually absorbed, and the resulting void is filled by serous exudation. Finally, secondary degenerations are rare.

Clinically the difference seems still greater, since in the new-born the lesion is latent and cannot be diagnosed, whilst in the aged it manifests itself by striking and ordinarily characteristic symptoms. In the pathogenesis the dissimilarity is no less marked, for in advanced age the point of departure of the softening, except in rare cases, is in the obstruction of the arterial system by atheroma, thrombosis, or embolism; whilst in the first days of life it is in the blood, whether it acts directly by the formation of clots or by nourishing insufficiently the nerve-substance.

If this comparison exhibits many points of difference, it is because we have so far only examined the details, whereas if we seek the source of the malady we will find it to be the same in both cases.

In short, the arterial or cardiac lesions which in the aged produce thrombosis or embolism are the consequence of the inevitable defects of nutrition which are entailed on long life. In the new-born it is also a profound disturbance of the nutritive process which, through the blood, induces the disintegration of an organ of which time has not yet corrected the natural softness.

The points of pathological anatomy and pathogeny to which this memoir is devoted having only been glanced at by former writers, and as these are based on personal observation, we believe we may regard this as an original work, and consider the following propositions as hereby established:

1. The encephalon of the new-born is normally ex-

ceedingly soft, because cells abound in the reticulum, and the true nerve-elements, particularly the tubes of myeline, exist in very small proportion.

2. Predisposed in this way, softening is easily produced during life from pathological, and after death by physical, influences.

3. Post-mortem softening is distinguished by the odor of sulphuretted hydrogen, and the whitish-gray spots, full of vibriones, generally caused by a tardy autopsy, and an elevated temperature.

4. Pathological softening is of two principal forms:

a. Multinodal white softening, connected with fatty brain, of which it is the last stage, which has its seat almost exclusively in the centres of the hemispheres.

b. Red softening, which invades the same regions, but to greater extent, and is accompanied by capillary hemorrhage.

5. These two kinds of softening, which ordinarily exist apart, may co-exist.

6. Other lesions frequently accompany, and are intimately connected with, the preceding.

a. Intra-cranial,—old clots in the sinuses and veins of the pia mater, with a sub-arachnoid and peri-venous yellowish exudation, consisting of leucocytes and granules of protein.

b. The blood and different viscera are affected, especially the digestive tube.

7. Inanition is the usual and most certain cause of new-born encephalic softening.

8. In the majority of cases the brain-symptoms observed during life were uncertain, and in no case could a diagnosis be made from them.

9. Encephalic softening of the new-born may be observed with all its phenomena in the foetus and in infants of several months, but in the latter case its début dates back to a period near to birth.

10. When the lesion is old and extensive, it may produce—

a. Secondary degeneration of the pons Varolii, medulla, and spinal cord.

b. An intra-cranial effusion, with or without development of hydrocephalus.

11. Encephalic softening is very frequent at the two extremes of life; and, whatever points of undeniable dissimilarity exist in the lesion itself and the symptoms, its first cause appears to be identical, and consists, in the new-born as in the aged, in a *failure of nutrition*.

GLYCERIN OF BORAX IN FACIAL ERYSIPELAS.—Prof. D. M. Salazar, of the Hospital Nacional, Madrid, reports that he has cured eight cases of facial erysipelas in forty-eight hours by this remedy. Notwithstanding the rapidity with which the affection disappeared, there were no consecutive pathological affections. In one case the disease had existed three days before treatment was commenced, and there were bilious vomiting, intense cephalalgia, high fever, inflammation of the entire face, and some phlyctenulae in the vicinity of the right lower eyelid and the root of the nose. He applied the solution to the diseased parts with a brush, and then covered them with a mask of raw cotton. After twenty-four hours all the symptoms, local and general, were notably diminished, and the next day all the phlyctenulae had disappeared and desquamation was commencing.—*El Amfit. Anat. Españ.*, March, 1873.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 8, 1873.

EDITORIAL.

PROFESSIONAL ADVERTISEMENT.

THE idea or theory upon which the modern practice of advertisement is founded, we take to be this: John Jones has something that Joseph Smith wants; but if Joseph Smith does not know who has the article, John Jones can't get rid of it. Hence John advertises to let Joseph know where to find what he wants.

This is the original idea of advertisement. But of recent times traders have gone a step beyond it, and advertise for the purpose of creating a want in buyers,—and, undoubtedly, do so with success. Joseph has been contented with his old pantaloons, or with his worn entry oil-cloth, but is moved to discontent by the skilfully-worded paragraphs of John, and a new pair of pantaloons, or, perhaps, a “wooden carpet” or tiled floor, can alone still the unrest in his bosom.

All this may be well,—may make business lively. We have no concern with this: the question of interest to us is, How far is it proper or expedient for the profession to use the methods of trade? Seemingly, there is nothing wrong in Dr. Brown's telling his neighbors through the columns of the daily paper that if they wish his services they can have them. The trouble seems to be that if the doctor does this, the temptation to do more is such that average medical human nature can't resist it. Dr. Brown will very innocently tell his neighbors that he has paid especial attention to diseases of the

genito-urinary organs; has been educated under Sir William this, or that, abroad; studied in this or that hospital: all true, perhaps, but very demoralizing for a man to publish of himself. He who commences in the most hesitating plaintive tones to blow his own trumpet in the public press will, by-and-by, end in a brazen blast rivalling that which shook the walls of Jericho.

This is human nature. Well, therefore, does the code of the American Medical Association read,—

“§ 3. It is derogatory to the dignity of the profession to resort to public advertisements, or private cards or handbills, inviting the attention of individuals affected with particular diseases,—publicly offering advice and medicine to the poor gratis, or promising radical cures; or to publish cases and operations in the daily prints, or suffer such publications to be made; to invite laymen to be present at operations; to boast of cures and remedies; to adduce certificates of skill and success, or to perform any other similar acts. These are the ordinary practices of empirics, and are highly reprehensible in a regular physician.”

It is evident, however, that in some way or other a physician must be known before he can be employed. Of course the chief way in which, in the generality of cases, the reputation of a physician grows is by the word of mouth of his patients. There are, however, various indirect methods of advertising, some of which are not only legitimate and honorable, but, from the nature of the case, unpreventable. A portion of the value of positions in hospitals, medical schools, and other public institutions arises from the advertisement which they give to those who hold them,—endorsing them before the public as men of skill and attainments in their profession. Again, writing is a method of indirect advertisement. Articles in medical journals, medical monographs, and other works, of course publish their authors primarily and chiefly among the profession, but to a certain extent also among the people.

The value of such indirect advertisement is shown by the bitter controversy which has recently taken place in London in regard to the propriety of professional men “making known in a genteel way” that they are the authors of works on especial subjects in medicine. It has been the custom in the city named, when a physician writes a work on this or that specialty, to advertise the book extensively in the *London Times* and other secular papers, and even to put out placards of the same in the streets, ostensibly for the purpose of selling the book, really with the design of making the public aware that Dr. Jones is authority as an aurist, oculist, chiropodist,

or what may be. Now, the Council of the London College have recently condemned this proceeding, prohibiting the members from advertising their books in this way; and their action has given rise to some plain talking. It has been freely asserted that the established physicians who constitute the Council, desiring to maintain the undisputed possession of their respective cocklofts, have kicked away the ladder up which they have climbed. One "medicus" asserts that to stop advertising his books would "retard his advance in practice ten years, and keep him starving," and pointedly calls attention to the fact that the works of Mr. Curling, President of the College, have been advertised to such an extent as to make Curling and testis household words in the community, and consequently to establish their author. Another correspondent alludes pleasantly to the circumstance that the London *Lancet*, which has strenuously upheld the Council, placards the railway stations with the titles of communications on "Tumors of the Womb," "Rectum," and other subjects generally supposed not to offer edifying reading for mixed companies of ladies and gentlemen. The upshot of the controversy, so far as can be judged at this distance, will be that authors will sell their works to publishers, with the secret understanding that they shall be advertised, and then defend themselves before the College as having no control over their books. Indeed, the defence offered for the president in the matter already alluded to seems to us to amount to this.

In this country this avenue to practice has as yet scarcely been opened, even as a corduroy road. A mine that has been worked and found to contain golden ore is writing for popular magazines articles on subjects so closely allied to medicine as to put their authors in a favorable light before the public. This practice is certainly not to be condemned altogether. If a physician have anything new to say that the public ought to hear, and can say it well enough to command attention, it is his duty to say it; but any one who is anxious to preserve absolutely unspotted his record before his fellows will remember that he is treading on dangerous ground, and mind very carefully his steps, so as to avoid even the appearance of evil,—will take care that his articles show that he has a message to deliver, and is not simply writing for personal aggrandizement.

Courts of justice have afforded some physicians first-rate opportunities for displaying their charms; and, whilst our profession has been honored by the modest knowledge and wisdom of such men as Dr. Ray, it has been no less disgraced by the per-

formances of others. If the published accounts be true, in a neighboring city, not long since, leaders of the profession belittled themselves and their associates by a so-called "public exhibition of anæsthesia;" an exhibition out of which, apparently, could come only one good,—the advertisement of the performers. "As the old cocks crow the young ones learn." The legitimate results of sowing such seed, it seems to us, will be a crop of public performances in surgery, dissections, physiological experimentation, lectures on marriage, health, disease, sexual life,—one and everything that can attract the crowd; performances that have hitherto been considered among the perquisites of abandoned quacks.

Space is wanting for a further discussion of these general points: indeed, such discussion seems unnecessary. It is so evident as to be trite, that there are proper and justifiable—nay, inevitable—methods of indirect advertisement,—advertisement that will largely aid in leading to fortune. Now, it is almost equally evident that these paths are especially open to the favored few who, by ability or culture, are fitted to be leaders, and to those who, by large social, religious, or other influence, can obtain public positions. Taking these assertions as truisms, remembering the qualities of human nature, the deduction is inevitable that, unless great care be exercised, these indirect advertisements will slowly but surely undermine the good feeling and the high tone of our profession. For, if those less favored in obtaining wide-spread publicity are to be content, it can only be by the exercise of the most scrupulous care on the part of the more favored. If the humble Dr. Jones finds that his patients are attracted by the baits and caught in the nets most skilfully spread by the aristocratic Dr. Smith, whose clinics he attends at the public hospitals and under whose presiding he sits at the medical societies, surely under these circumstances Dr. Jones were more than human if he did not conjure his brains to find out some plan by which he too could gather fishes; and, being less favored than Dr. Smith by position and ingenuity, he will probably employ more clumsy, less plausible, less indirect methods of making himself known, and thus the process of deterioration will commence.

We suppose it will not be disputed that the medical profession in Philadelphia has in the past been pre-eminently conservative, pre-eminently high-toned. It is more comfortable to remain in the belief that our good qualities are being handed down from sire to son than to doubt their permanency,—more pleasant, like Mrs. Jellyby, to occupy

ourselves with the short-comings of our neighbors, looking so earnestly at the heathen of Boorioboola-Gha as not to see those at our doors, than to examine closely our own short-comings,—more comfortable and more pleasant, but not always more profitable. It seems to us that the process of deterioration has commenced in Philadelphia; and, as space is apparently wanting to enter fully into this subject, further discussion must be postponed until our next issue.

WE print in another column an account of a death which recently occurred in London during the administration of ether. The phenomena, as detailed, are so peculiar—so different from anything we have ever seen during the administration of ether—that we cannot help suspecting the purity of the ether. Be this as it may, although this single addition to the ether mortality list affords an increase to the latter of many per cent., yet it does not shake our faith at all in the comparative, almost absolute, safety of the Boston anæsthetic. We spoke, in a recent editorial, of the probably great number of unreported cases of fatal chloroform-narcosis, instancing two in this city we knew of: since then, we have been informed of two more, occurring in the practice of a single surgeon.

DR. LEVIS'S operation, which we noticed some weeks since, is apparently a success so far as the aneurism itself is concerned. The tumor has become very hard, and pulsation in it, as in the radial and axillary arteries, has ceased. No local irritation has occurred in or about the aneurism since the operation, nor any inconvenience from arrest of circulation through the subclavian and the axillary, and its diversion to other channels. Pain has been almost entirely relieved. The patient's only inconveniences seem now referable to pressure of the consolidated mass of the aneurism on the upper part of the right lung, impeding its circulation and producing engorgement. As a consequence the patient has been expectorating mucus darkly colored with blood.

ON Wednesday last a week Dr. F. F. Maury cut the brachial plexus in the case of superficial neuroma reported in the last number of *Hays's Journal*. The patient is doing well, but the relief has only reached the lower two-thirds of the affected skin, the remainder evidently being supplied by the cervical nerves.

OUR namesake "*The Medical Times*" (Canada) certainly does honor to us in other ways than by adopting our title. One-third of the number just received, we see, is taken from our columns. The editor of *The Medical Times* is certainly a sensible man,—knows what is valuable and readable.

CORRESPONDENCE.

LONDON LETTER.

[From Our Own Correspondent.]

The Month of Congresses—The British Association for the Advancement of Science—The School of British Physiologists—Their Divergencies—Dr. Rutherford's Address to the Section of Physiology—Dr. Ferrier's Researches in the Functions of the Brain—Revolution in Cerebral Physiology—Confirmation of the Pathological Views of Dr. Ferrier—The Pharmaceutical Conference—The Position of Pharmacists in Great Britain—Their Education, Views, and Political Influence—Their Leaders—Unusual Doses—The Medical Schools.

LONDON, October 3, 1873.

THE months of August and September are essentially "Congress" months in this country. The "season" is over; all London is out of town; and not only all London, but all the inhabitants of great cities, are taking holiday. Hence the peripatetic associations which have become so numerous in this country, and which are becoming hardly less numerous abroad, choose August and September as the most convenient months in which to rally their scattered members. Besides the British Medical Association, we have had the meetings of the British Association (at Bradford), of the Pharmaceutical Conference, and of the Social Science Association at Norwich, at all of which matters of interest to medical readers have come under discussion. The Section of Physiology at the British Association generally produces matters of interest to medical science. It was this year under the presidency of Dr. Rutherford, Professor of Physiology at King's College; and his address was mainly upon the importance of physiology as a preliminary medical study, and as one to which medical science must look for its chief elements of progress in the future. There is, it may be mentioned, a certain party here among our younger physiologists who are rather jealous of the association of physiology with medicine, and who are disposed to divorce it, if possible, from medicine, with the idea of making it assume in universities the dignity of a separate and abstract science. Among these may be mentioned Huxley, Michael Foster, Ray Lankester, and the whole school of physical and zoological physiologists. To these are opposed, in this respect, Sharpey, Burdon-Sanderson, Hughes Bennett, Rutherford, Gamgee, Ferrier, Lauder-Brunton, and others who are actively engaged in the revival of experimental physiology as a favorite and necessary study in our medical schools. There is no question that it had fallen greatly into neglect during the past quarter of a century; and as Virchow pointed out in his address to the British,

Medical Association in August, this was especially surprising and regrettable in the country which had produced in the beginning of the century Hunter, Bell, and Marshall Hall, and had given the signal on the Continent for the vigorous prosecution of physiological research. The revival of such studies was in this country greatly due to the energy of Hughes Bennett. It is from the Edinburgh school that Sharpey, Burdon-Sanderson, Ferrier, Mr. Kendrick, Arthur Gamgee, Rutherford, and Lauder-Brunton have proceeded; Michael Foster is the immediate pupil of Sharpey; and the physiologists named are now all in their turn teachers, and are building up schools of experimental physiology which are already producing apt and able scholars, such as Garrod, Galabris, Galton, and Mosely,—young men of the highest promise, of whose names you will hear more as the years roll on. Dr. Rutherford has an especial right to dwell upon the close connection between experimental physiology and medical study, because he has done more than most others to revive it in this country.

The most interesting topic discussed in the Section of Physiology at Bradford were the remarkable recent researches of Dr. Ferrier, of King's College, on the subject of the Functions of the Brain. These researches, of which the first conclusions were published in the *British Medical Journal* of April 26, and of which a fuller account will be found in the recently published volume of Transactions of the West Riding Asylum, have deservedly attracted a very great share of attention from British physiologists. They are, indeed, of so remarkable a character, and will so largely revolutionize our views of cerebral physiology, that the briefly-stated conclusions just published were regarded with considerable incredulity. But as the method employed was more clearly explained, and the experiments were witnessed by competent observers, they were found to be quite trustworthy; and Sharpey, Rutherford, Sanderson, and Brunton have concurred in describing them as the most remarkable and important researches for years prosecuted in the department of cerebral physiology. They have been the subject of leaders in the *Times* and other daily papers; and the effect of the attention directed to the subject has been to set every one reading the West Riding Reports, where the full particulars are given. Briefly, Professor Ferrier's method of proceeding has been to remove the skull-cap of living animals under chloroform and to faradize the special convolutions of the brain. The result has been not only to modify our view of the functions of the parts of the brain, but to show a definite localization of function beyond what had been anticipated since the destruction of the so-called phrenological system by the demonstration of its errors of interpretation, and to confirm in a remarkable degree the pathological conclusions at which Dr. Hughlings Jackson has laboriously arrived by a series of clinical and post-mortem investigations which have attracted but too limited attention, but which will assuredly live in the history of medicine as affording data of first-rate im-

portance. I will venture to transcribe from the *London Medical Record* a summary of the more important conclusions of Ferrier, as being the most novel and interesting matters of research at this moment under medical notice:

"1. The anterior portions of the cerebral hemisphere are the chief centres of voluntary motion and the active outward manifestation of intelligence.

"2. The individual convolutions are separate and distinct centres; and in certain definite groups of convolutions (to some extent indicated by the researches of Fritsch and Hitzig), and in corresponding regions of non-convoluted brains, are localized the centres for the various movements of the eyelids, the face, the mouth, the ear, the neck, the hand, foot, and tail. Striking differences corresponding with the habits of the animal are to be found in the differentiation of the centres. Thus, the centres for the tail in dogs, the paw in cats, and the lips and mouth in rabbits, are highly differentiated and pronounced.

"3. The action of the hemispheres is in general crossed; but certain movements of the mouth, tongue, and neck are bilaterally co-ordinated from each cerebral hemisphere.

"4. The proximate causes of the different epilepsies are, as Dr. Hughlings Jackson supposes, 'discharging lesions' of the different centres in the cerebral hemispheres. The affection may be limited artificially to one muscle, or group of muscles, or may be made to involve all the muscles represented in the cerebral hemispheres, with foaming at the mouth, biting of the tongue, and loss of consciousness. When induced artificially in animals, the affection, as a rule, first invades the muscles most in voluntary use, in striking harmony with the clinical observations of Dr. Hughlings Jackson.

"5. Chorea is of the same nature as epilepsy, dependent on momentary discharging lesions of the individual cerebral centres. In this respect Dr. Hughlings Jackson's views are again experimentally confirmed.

"6. The corpora striata have crossed action, and are centres for the muscles of the opposite side of the body. Powerful irritation of one causes rigid pleurosthotonos, the flexors predominating over the extensors.

"7. The optic thalamus, fornix, hippocampus major, and the convolutions grouped around it, have no motor signification.

"8. The optic lobes or corpora quadrigemina, besides being concerned with vision and the movements of the iris, are centres for the extensor muscles of the head, trunk, and legs. Irritation of these centres causes rigid opisthotonos.

"9. The cerebellum is the co-ordinating centre for the muscles of the eyeball. Each separate lobule (in rabbits) is a distinct centre for special alterations of the optic axes.

"10. On the integrity of these centres depends the maintenance of the equilibrium of the body.

"11. Nystagmus, or oscillation of the eyeballs, is an epileptiform affection of the cerebellar oculo-motorial centres.

"12. These results explain many hitherto obscure symptoms of cerebral disease, and enable us to localize with greater certainty many forms of cerebral lesion."

At the Pharmaceutical Conference a great number of pharmaceutical chemists assembled to discuss points of more or less general interest. The dispensing chemists of this country are now a very numerous and influential body, and their influence is increasing. Since the passing of the Pharmacy Act, no one can sell toxic substances and dispense medicines without passing an examination on the ordinary preliminary subjects of education, including an elementary knowledge of Latin, and subsequent examinations in pharmacy, chemistry, and botany. The "minor" examination is, of course, a barely respectable minimum; but the "major" examination is one of fair stringency, and no really ignorant person, no man not fairly conversant with pharmaceutical knowledge, can enter into business as a chemist. This has necessarily done a good deal to give compactness, unity, and respectability to the trade. It puts it in some respects on a par with professions, and converts it into a monopoly. The trade is subject, in some degree, to government supervision, and the Privy Council has a veto on all regulations affecting the examinations, and nominates a visitor to inspect the examinations. The power of the government over the trade is, however, limited in theory, and in practice still more so, by the parliamentary organization of the pharmacists, and their influence in the legislature, which, like that of all numerous and compact bodies, is, when deftly wielded, considerable. It was the wish of the medical profession and of the leading pharmacists that the druggists should all adopt some sort of mechanical precaution to prevent the frequent recurrence of accidental poisoning. There was, indeed, an understanding with the government when the Pharmacy Act was passed that the Pharmaceutical Society, which is the controlling body among the pharmacists, would impose the use of "fluted bottles" in dispensing lotions and poisonous medicines, as a rule obligatory on all dispensing chemists. The council issued rules accordingly, but they were overthrown by the popular vote; and when the government subsequently introduced a supplementary bill into Parliament to enforce such a rule it was met with so much opposition that it was quietly dropped. I mention this short history to illustrate the strong position which English pharmacists now hold. On the whole, it must be said that they use it well. Counter-practice and irregular prescribing prevail to a considerable extent in the poorer neighborhoods and in country places, but are discouraged by the leaders in the trade, and, in theory, are always reprobated as they should be. Practically, among the poorer classes it is difficult to put a stop to them. They cannot well afford to pay medical fees for advice as well as for medicines; and possibly the sort of advice and medicine they get at the druggist's shop (or, as they call it, the doctor's shop) for a few pence meets their necessities and the hard conditions imposed by their poverty better than any other would do which can at present be devised.

The leading pharmacists here are J. Hyde Hills, W. Sandford, Carteighe, Morson, Savory, etc. They are public-spirited and able men. Mr. Hills holds an exceptionally good position as the personal friend of many of the leading physicians and surgeons of the day, and is a thoroughly trustworthy and honorable man. Mr. Sandford is the orator of the company, and varies in his addresses from the sublime to the ridiculous. He is hot-tempered and wrong-headed, and lately led an ill-advised opposition to the admission of women to the Pharmaceutical Society, which has brought the society into some discredit. But it would be difficult to find any society of retail shop-keepers who conduct their affairs, on the whole, with more dignity and public spirit than the druggists of Great Britain.

The recent condemnation of a druggist for refusing to dispense an (intentionally) large dose of digitalis prescribed for a patient in delirium tremens has led to much discussion, the patient having died, and the druggist being censured by a coroner's jury. This case was considered at the conference, and a resolution was passed asking medical men when they prescribe unusual doses always to initial the dose, in order to indicate intention, and in all cases to sign their prescriptions with their full name instead of their initials. The object of the latter request is to enable the dispenser to communicate with the prescriber privately when he has any doubt, or when he believes that a *lapsus calami* has occurred.

While I write, the introductory lectures are being delivered at the medical schools, and the schools are re-opening for the winter session. They will, no doubt, furnish material for my next letter.

NOTE ON LANCING THE GUMS IN DIFFICULT DENTITION.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES.

DEAR SIR,—The excellent communication of Dr. James W. White upon Pathological Dentition, and the valuable extract from an incisive article of Dr. J. Foster Flagg's, have brought the subject of cutting the gums in children whilst teething so prominently before your readers that I think perhaps an incident from my own experience may be interesting enough to warrant its publication in your columns. From the circumstance that the little patients in these cases are generally too young to appreciate our efforts for the mitigation of their sufferings by the aid of the gum lancet, any subjective facts in favor of operations of this character must necessarily be rare, or at least difficult to collect; but, as a nucleus for the aggregation of such testimony, permit me to report the following.

My youngest child, a little girl, commenced to teethe after attaining the age of one year, and suffered severely during the process, often obtaining apparent relief, however, from free incisions into the tense and swollen gums. On one of the latter of these occasions, when she was about twenty-six months old, I found, on re-

turning near midnight from a late visit, that she had been awake and fretful most of the evening, complaining at short intervals of her teeth. Upon my entering the chamber, she at once (to the profound surprise of her mother and astonishment of the nurse) cried out, as well as she could between her sobs, "Papa, lance 'em! papa, lance 'em!" and bravely held open her mouth for the operation. When performed, this was followed, as the poor child had learned to expect, by such prompt and complete ease that she soon sank into a quiet slumber, which continued until morning, forming a marked contrast—most agreeable for all concerned—to the distressed restlessness she displayed up to the moment of incising her gums.

Very respectfully yours, etc.,

JOSEPH G. RICHARDSON, M.D.

No. 1620 CHESTNUT STREET, PHILADELPHIA.

GLEANINGS FROM OUR EXCHANGES.

DEATH FROM THE INHALATION OF ETHER.—We have this week to make the sad announcement of a death from the inhalation of ether. It occurred at the Royal South Hants Infirmary. We shall be glad of the comment of Dr. Morgan and of our Boston contemporaries. David Newman, aged 14, a strumous lad, who had suffered from repeated attacks of cornitis, was admitted an in-patient of the above institution on September 25, 1873, under the care of Dr. Lake. On Wednesday, October 1, he was brought into the operating-room in order that iridectomy might be performed. When on the table he exhibited considerable alarm, and required some persuasion before he was induced to lie down. Dr. Griffin having taken charge of the pulse, half an ounce of ether was poured on a sponge contained in a cone of spongio-piline, and the latter was closely applied to the mouth and nose. After a few minutes' inhalation, the ether being nearly exhausted, three drachms more were poured on the sponge. Shortly after commencing to inhale this second quantity he began to struggle violently, getting at length into a state bordering on opisthotonos, his face becoming intensely scarlet. Dr. Griffin then announced that his pulse, which up to this time had been perfectly natural, had become very feeble. The ether was at once discontinued, when, the pulse having improved, Dr. Lake operated, no more ether being administered. At the close of the operation, which occupied only a few seconds in its performance, and before the eye could be bandaged, the pulse became imperceptible, the breathing was suspended, and the countenance livid. The tongue was drawn well out of the mouth and held there, the calves of the legs were vigorously flagellated, and the chest freely slapped with a wet towel. The effect of these measures was to cause the patient to respire freely, to cry out lustily, and to kick about on the table; but this improvement did not last long,—probably about a minute. The pulse at the wrist did not return, and the breathing again stopped. Artificial respiration—at first by Silvester's method, afterwards by Marshall Hall's—was then had recourse to; at the same time an intermittent current of faradic electricity was passed in the course of the phrenic nerve; this at first caused strong periodic contractions of the respiratory muscles; but after about ten minutes or a quarter of an hour these ceased to respond to the current, and it became evident that life was extinct. These measures were, however,

still persevered with for about three-quarters of an hour. At the necropsy, twenty-one hours afterwards, the brain was found to be healthy, and not much congested. The right cavities of the heart were full of dark fluid blood, but the left cavities contained only about a drachm of a similar fluid. The valves were healthy. The muscular structure, although somewhat flabby, presented no decided evidence of fatty degeneration. The lungs were congested, and of a somewhat bright red color. The other organs were healthy. —*British Medical Journal.*

DILATATION OF THE CERVIX UTERI IN DYSMENORRHEA (*New York Medical Journal*, October, 1873).—Dr. John Ball recommends the following method of procedure in cases of constricted cervix uteri. Having procured the thorough evacuation of the bowels of the patient, place her upon her back, with the hips near the edge of the bed, and when she is profoundly anesthetized introduce a three-bladed, self-retaining speculum; seize the os uteri with a double-hooked tenaculum; draw it down towards the vulva, and then introduce a metal bougie as large as the canal will admit, following it in rapid succession by others of larger size, until one is reached which represents the size of the dilator. Then insert the dilator and stretch the cervix in every direction until it is enlarged sufficiently to admit a No. 16 bougie, which is all that is generally necessary. Then introduce a hollow gum-elastic uterine pessary of about that size, and retain it in position, by a stem secured outside the vulva, for about a week, in which time it has done its work and is ready to be removed. During this time the patient should be kept perfectly quiet, and usually upon her back. Dr. Ball claims that the operation saves a great deal of time, causes much less constitutional disturbance than the use of tents, and is not only safer than the metrotome, but is free from some serious objections to the use of the latter, there being no resulting cicatrix to interfere with the dilatation of the parts, and the condition of the patient after an unsuccessful operation being no worse than before. He says that it relieves the constriction entirely, by breaking up all the adhesions, which are often firm and unyielding; that, acting as a derivative, it cures the hyperæmia of the cervix; and that, further, it establishes a radical change in the nutrition of the whole organ.

He details nine cases of stricture of the os and cervix complicated with vaginismus, chronic endo-cervicitis, version, sterility, dysmenorrhœa, etc., in all of which very great relief or permanent restoration to health was effected by rapid and forcible dilatation. In a foot-note the editor of the *New York Medical Journal* quotes Dr. Ellinger, of Stuttgart, as recommending the operation,—1, in stricture of the cervical canal; 2, stenosis due to flexions; 3, metrorrhagia in a flabby, swollen uterus, but without new growths; 4, retained catarrhal secretions; 5, for exploration of the uterine cavity; 6, replacement of a flexed uterus; 7, sterility. Dr. Ellinger declares that he has never had reason to regret rapid dilatation, and urges it, where dilatation is justifiable at all, to the exclusion of all other methods.

THE CAUSES OF DEATH AFTER SEVERE SUPERFICIAL BURNS.—This question is discussed at considerable length by Dr. Mendel, of Paukow, in the *Vierteljahrssch. für ger. u. off. Med.* (xiii. 1). It is a familiar fact that a superficial burn involving more than one-half of the surface of the body is pretty sure to be fatal, while death may be expected in a majority of cases where only one-third of the body is burnt. Death may ensue at three different stages of the wound,—the periods of irritation, inflammation, and suppuration,—and at each different stage the mode of death is different.

1. *Causes of Death in the Period of Irritation.*

a. *Paralysis of the Central Nervous System.*—This is probably the result of the shock experienced by the nervous system at the time of the reception of the burn. It is of brief duration, and often passes unnoticed.

b. *Congestion of the Internal Organs.*—Immediately after the accident, a reaction, more or less violent, takes place, characterized by congestion of the encephalon and its membranes, of the lungs and pleura, and also of the alimentary canal and peritoneum, accompanied often by sanguineous exudations upon the lungs and heart.

2. *Causes of Death in the Stage of Inflammation.*—

These are the internal inflammations induced by the cutaneous inflammation, and having their seat, commonly, in that organ situated the nearest to the burn. Meningitis and encephalitis are relatively rare; pneumonia is much more frequent, as are also pleurisy and pericarditis. Gastro-intestinal inflammation is an unusual accompaniment, and, when it occurs, its seat is usually in the duodenum. Another lesion, noticed almost invariably in the duodenum, is *ulceration*, analogous to the round ulcer found in the stomach. This may advance to perforation, and thus induce peritonitis, or the destruction of a vessel may take place, and death may then result from hemorrhage. To account for the peculiar localization of this lesion, we are forced to resort to various hypotheses; some pathologists connecting it with the situation of Brunner's glands, others ascribing the ulceration to embolism, and others still to some chemical change in the constituents of the bile. In some instances, tetanus has been observed in this stage of a burn.

3. *Causes of Death in the Stage of Suppuration.*—

These are exhaustion, pyæmia, septicæmia, renal disturbance accompanied by anasarca, and intestinal hemorrhages.

Death has been known to take place suddenly, without any appreciable cause, even after complete cicatrization of the wound had taken place.—*Boston Medical and Surgical Journal*.

MISCELLANY.

DR. NÉLATON, who has just died, lingered for several weeks, and suffered a good deal. He knew of his condition during this time, and often repeated the remark, "Death is long in coming." During the few days before his death he received three letters from the ex-Empress and her son, dated at Chiselhurst, and he read each of them several times. The last letter of the Empress contained the following postscript: "I reopen my letter to tell you that the Prince, before leaving for Woolwich, begged to be remembered to you." The night before his death he said to his son, "Do as much good as you can in life,—above all, without noise." The first phrase in his will is thus written: "I desire that my wife shall bring up my son to respect religion, honor, and work." His codicil expressly requested that no discourse should be pronounced over his tomb, and that the funeral should be as simple as possible. By taste, and somewhat through vanity, he avoided a display of instruments in his operations: he called it "surgery with a big orchestra." He had a small, dry hand, with pointed fingers and a long thumb: this hand was his principal instrument. His coolness equalled

his dexterity. "When you have a correct diagnosis, you know where you are going, and you don't risk anything," said he. One day, after homœopathy had secured a foothold in France, a doctor of that school, rubbing his hands with exultation, said to Nélaton, "You see, we are gaining ground every day." "Yes,—in the cemeteries," added he. The Emperor said to him, when he cured his son in 1867, "I thank you, Monsieur Nélaton; you have saved my son." "I am glad of it, sire," was his answer, "for I have at the same time saved my reputation." Dupuytren, the greatest genius in the science of surgery of modern times, was his master. The pupil did not equal the master, but he had a greater number of clients among distinguished people. He was a hard worker, and gifted with a rare intelligence. He possessed, too, a certain talent for elocution which tempted him to compete for the professorship of the surgical clinic. He failed the first time, in 1850, but the second time, in 1851, he won, and the occasion was memorable on account of the number and character of his competitors. The faculty of the college had reason to congratulate itself on having attached him to the institution. His teaching was brilliant, and he drew around him a numerous following of studious young men. His successes in the hospital, the certainty and the precision of his diagnosis, his sure judgment and astonishing dexterity, all joined to much gentleness of manner towards patients, soon created for him a great reputation. He became the surgeon of Louis Napoleon; extracted the ball from Garibaldi,—the story of which is now legendary,—and honors reached him from all sides. Clients came to him in such numbers that he was obliged to give up his professorship. Soon after he was made Senator and Grand Officer of the Legion of Honor; Royer, Michel Lévy, and Ricord being the only other physicians who have received this honorable distinction. Science is indebted to him for some modifications in operating. He has given his name to a process for setting the shoulder, and another for the elbow, also to one called the *taille de Nélaton*. The rigors of the siege of Paris contributed to his death, and he finally succumbed to an organic disease of the heart from which he had long suffered.—*Paris Letter to New York Tribune*.

TO RESTORE COLOR TO FABRICS.—When color on a fabric has been accidentally or otherwise destroyed by acid, ammonia is applied to neutralize the same, after which an application of chloroform will, in almost all cases, restore the original color. The application of ammonia is common, but that of chloroform is little known. Chloroform will also remove paint from a garment, or elsewhere, when benzole or bisulphide of carbon fails.—*American Artisan*.

THE student who was asked the use of starch in germination, and who replied that, "In the German nation, as elsewhere, starch is used for doing up linen and similar laundry purposes," intends to take an extra course of botany during summer vacation.—*Boston Journal of Chemistry*.

PATRONESSES OF QUACKERY.—Since the days of St. John Long, when duchesses entered the witness-box to depose to the marvellous effects of that impostor's liniment, there has always been an irresistible attraction for the ladies of the upper ten thousand in any delicate bit of quackery. Globules are *distingué*. There is none of the grossness or materialistic appearance which belongs to an apothecary's bottle,—globules and dilutions being to medicine what the fragrance of an herb is to its medical potency. It is interesting to be in delicate health, and under homœopathic guidance that ladylike characteristic may be indulged without the discomforts of nasty bottles. Accordingly, the *crème de la crème* are, at least, professing homœopaths; and we observe from the prospectus of a Homœopathic Bazaar that titled patronesses are neither scarce nor undistinguished. H.R.H. the Duchess of Cambridge leads off, supported by five other duchesses. Five marchionesses follow, among whom are especially notable the Marchioness of Westminster and the Marquise de Caux (Madame Adelina Patti). Next we have ten countesses and nine viscountesses, the Countess Granville leading this division. Then we find about fifty "ladies" or "baronesses," including such names as Ebury, Elcho, Lawrence, Rothschild, Seymour, Havelock, Erskine, etc. The mere honorable and untitled ladies who bring up the rear are grand enough to shed lustre on any ordinary cause, including as they do such names as Mrs. Milner Gibson, Mrs. Knatchbull-Hugessen, and others whose husbands' names are linked with wealth, talent, or fashion.—*Dublin Medical Press and Circular*.

OPIUM-LAND pays a price in Malwa unknown in any other part of India. Meadow-land about a market town in England is scarcely more remunerative to landlords than thousands of square miles blooming with the poppy are to the chiefs of Malwa.—*The Clinic*.

WHY is a tom-cat like a surgeon? Because they both mew-till-late.

THE following may be regarded as representing tolerably accurately the number of new students at the metropolitan medical schools this year: St. Bartholomew's, 105; Guy's, 90; University College, 83; St. Thomas's, 55; King's College, 40; Middlesex, 38; St. George's, 37; London, 32; St. Mary's, 21; Charing-Cross, 15; and Westminster, 10.—*London Lancet*.

CHAUTAUQUA COUNTY MEDICAL SOCIETY, NEW YORK.—At the annual meeting held at Dunkirk, N.Y., July 8, 1873, the following officers were elected for the ensuing year: President, Dr. A. Waterhouse, Jamestown, N.Y.; Vice-President, Dr. S. M. Smith, Dunkirk, N.Y.; Secretary and Treasurer, Dr. T. Charles Wilson, Portland, N.Y.

As illustrating the adroitness of many lunatics in concealing their illusions, it is related that the French novelist Balzac once became so much interested in a man whom he believed to be unjustly confined in an asylum as to carry the case before the courts and obtain a decree for his liberation. On the day of his release he invited

the man to breakfast with himself and a few friends. The invitation was so stoutly declined that Balzac demanded the reason, and at last extorted from the poor fellow that it was impossible for him to appear except at night, *because he was the moon*.—*Cincinnati Lancet and Observer*.

PRECOCIOUS DENTITION.—We read in *L'Union Médicale du Canada*, October, "Dr. C. M. Filiatrault, of this city (Montreal), informs us that during the past month he attended the accouchement of a woman who brought into the world a child whose two inferior incisors were pierced through at the moment of birth. It was a masculine child, and well formed. It is known that Louis XIV. was also provided with two teeth at the time of birth."—*Canada Medical Times*.

THE death of Sir Henry Holland is announced by telegraph in the daily papers.

SATURDAY, NOVEMBER 15, 1873.

ORIGINAL COMMUNICATIONS.

ON THE INHALATION OF NITROUS OXIDE, NITROGEN, HYDROGEN, AND OTHER GASES AND GASEOUS MIXTURES.

BY ELIHU THOMSON,

High School Laboratory, Philadelphia.

IN No. 100, vol. iii., of the *Medical Times*, appears a translation from the French of Drs. Jolyet and Blanche, on the protoxide of nitrogen, in regard to its effects upon living organisms. Having been independently pursuing the same or similar investigations for some time past, I take this opportunity of laying my results before those interested.

I was led to undertake the experiments described herein, by a consideration of the effects of the inhalation of nitrous oxide gas upon the different persons to whom I have seen it administered. There are certain marked effects produced by respiring nitrous oxide, which I believe are common to all persons,—certainly to those cases coming under my immediate notice.

The first marked effect of nitrous oxide inhalation is a quickening of respiratory movements, which effect continually increases up to the period of insensibility. In some cases the breathing is very rapid and laborious, two or three inspirations being made per second.

Another effect, that seems to be common to all cases, is that during the period of unconsciousness, so called, there is left scarcely more than a bare idea of existence: all other ideas seem to be obliterated. Another common effect is, that before the period of unconsciousness there is a confusion of ideas. The appearance of a person who has become unconscious from the inhalation of nitrous oxide is evidently that of asphyxia or suffocation. The countenance assumes a leaden hue, the eyes lose their lustre and have, instead, a vacant stare. These considerations led me to the conclusion that the effects, as above enumerated, were the results of true asphyxia, rendered bearable by there being furnished an inert gas with which the lungs may be filled and emptied as often as may be. The case may be compared to that of a hungry man satisfying the craving for food by eating clay or other inert substance, but who would certainly starve if the practice were continued, at the same time that he would require to make very frequent use of the clay to allay his hunger.

In order to become fully satisfied of the real state of the case,—that is, that the effects above cited are due to incipient suffocation or partial asphyxia,—a few experiments were tried.

It was naturally supposed that other inert gases, as hydrogen and nitrogen, should, if breathed, produce effects almost the same as those of the nitrous oxide, assuming the effects of the latter to be in reality due to asphyxia.

The following is an account of the experiments conducted, and the deductions from them:

Experiment I.—Pure hydrogen was prepared and placed in a small gas-bag, and breathed in the same manner as nitrous oxide is administered. A few seconds after commencing the inhalation, the breathing became rapid and labored, then a feeling of lightness ensued, followed by a decided confusion of ideas, an indescribable fluttering noise, a slight affection of sight, all tending to show the approach of unconsciousness.

The breathing of the hydrogen was discontinued just short of producing unconsciousness; and upon breathing air the return to a normal condition took place with great rapidity.

The above experiment was repeated by myself and another, with a recurrence of the same effects, which are evidently the results of partial asphyxia.

Experiment II.—A quantity of nearly pure nitrogen was prepared by a process not generally known, and, so far as I am aware, first employed by myself. When one volume of nitric oxide is mixed with four volumes of air, and the mixture thoroughly washed by water, about three and a quarter volumes of nitrogen are the result.

The nitrogen was breathed in the same manner as the hydrogen in the foregoing experiment, and was followed by the same effects, which, however, were produced much more slowly than in the case of hydrogen. The effects, too, were very much longer in passing off.

This latter fact is, doubtless, owing to the low diffusive power of nitrogen compared with that of hydrogen.

The effects of hydrogen and nitrogen, it will thus appear, do not differ from those of nitrous oxide. Of the three gases above mentioned, nitrous oxide is, in my judgment, least unpleasant to inhale, owing, probably, to its solubility in the blood giving it an exhilarative effect. It will, therefore, still continue to occupy the first rank in producing insensibility to pain.

It may be mentioned that in no case was any disagreeable after-effect produced by the inhalation of either hydrogen or nitrogen; and I am of the opinion that when the gas is shown to be pure there can be no danger for persons in sound health to make an experiment of this nature.

In order to test the matter in consideration still further, a few interesting experiments were instituted, as follows:

Experiment III.—A mixture of four parts by volume of hydrogen and one of oxygen was made. The mixture filled a large jar of a capacity of three and a half gallons.

A small kitten was then placed in the mixture, and the mouth of the jar tightly closed. The kitten manifested not the least inconvenience from breathing the mixture of hydrogen and oxygen, its effect not differing from that of common air, it being, indeed, air in which the nitrogen was replaced by another inert gas, hydrogen. The kitten remained in the jar fifteen minutes, when it was removed. It cannot be doubted that the limit to life exist-

ing in such a mixture would be when the greater part of the oxygen had been converted into carbonic acid. The gases remaining in the jar after the experiment were examined, and found to contain a notable quantity of carbonic acid. Another portion being fired by a lighted match exploded with considerable violence.

Experiment IV.—The same jar as used in the above experiment was again filled, but with pure hydrogen only, and the kitten placed in it as before. It immediately began gasping and showing signs of great inconvenience, and in less than fifteen seconds it had become motionless and insensible. On being brought into the air it recovered its normal condition in a few seconds. It gave no manifestation of pain on being pinched while insensible. In this experiment the insensibility is clearly seen to be due to asphyxia, or a want of oxygen, which was absent.

This experiment was repeated, coal-gas, well purified, being substituted for the hydrogen. Insensibility followed very rapidly, and on withdrawing the kitten from the jar it manifested no signs of vitality, except an irregular heart-action. The breathing had entirely ceased. Artificial respiration soon induced a succession of convulsive movements as of breathing, which gradually became regular, the kitten at the same time manifesting symptoms of returning vitality.

Consciousness was at last restored. There existed insensibility to pain up to the time of regaining consciousness. The experiment occupied about five minutes.

From this it would seem that coal-gas not only asphyxiates, but at the same time exerts a poisonous influence, causing entire cessation of breathing.

Experiment V.—A kitten was placed under the receiver of an air-pump and the air exhausted until the mercury in the barometer-gauge stood at six inches, which would leave but one-fifth the original amount of air in the receiver. The effects upon the kitten were nearly the same as with pure hydrogen (Exp. IV.), it soon falling over motionless and insensible. On allowing the air to re-enter the receiver, the kitten was restored in an exceedingly short space of time. This experiment was made with a view to comparing it with that which follows.

Experiment VI.—The same receiver, of capacity of about two and a half gallons, as used in Experiment V., was entirely exhausted of air and filled with pure oxygen gas. The kitten was then placed in the receiver so filled, and the oxygen exhausted until the mercury stood, as before, at six inches, leaving one-fifth the original weight of oxygen still in the receiver in an expanded state. In this partial vacuum the kitten remained twenty minutes, during the whole of which time it manifested not the least sign of inconvenience, sitting quietly, and showing attention when called or otherwise disturbed. The partial vacuum contained as much oxygen as is found in the same bulk of air. The vacuum was as good at the conclusion of the experiment as at the beginning.

This last experiment showed clearly that the rarefaction had no effect on the life-supporting

power, provided that the requisite amount of oxygen was present.

The above experiments lead me to adopt the following conclusions:

1. That the insensibility produced by the inhalation of nitrous oxide, nitrogen, hydrogen, and rarefied air is due to deficiency of oxygen, of which asphyxia is a result.

2. That the inert gases, nitrogen, hydrogen, etc., as well as a vacuum, are rendered capable of supporting life if a proportion of oxygen approaching that existing in common air be introduced.

I cannot agree with the conclusion of Messrs. Jolyet and Blanche that the respiration of nitrous oxide is at all dangerous if stopped at the proper time, for the experience of all who have used it shows that the asphyxia it produces leaves no harmful effects.

ON THE TREATMENT OF FRACTURES OF THE LOWER EXTREMITY OF THE RADIUS.

BY JOHN ASHHURST, JR., M.D.,

Surgeon to the Episcopal Hospital, Surgeon to the Children's Hospital, etc.

MORE than forty years ago Mr. Lonsdale enunciated the doctrine that fracture of the *shaft* of the radius should be treated by placing the forearm in a supine position, rather than in a position midway between supination and pronation, as was then, and as is still, done by the majority of surgeons. The reasoning by which Mr. Lonsdale enforced his opinion has always seemed to me just and conclusive, and his plan of treatment has met with the approval of many eminent authorities, among whom may be particularly mentioned M. Malgaigne, Mr. Callender, of London, Prof. Hamilton, of New York, and the late Prof. George C. Blackman, of Ohio. None of these gentlemen, however, with the exception of Mr. Callender, appears to have employed the supine position in the treatment of radial fracture, when the lesion has been situated below the point of insertion of the pronator radii teres. Mr. Callender extends the practice to all cases of fracture above the limits of the pronator quadratus, and by so doing has, in my judgment, taken a step decidedly in advance of his predecessors.

It is my object in this communication to go still further, and advise the employment of the supine position in the treatment of all cases of fractured radius, no matter what point of the bone may be involved, and whether the ulna is or is not also broken.

Some years ago I observed that more or less impairment of the power of supination remained after recovery in many of my cases of fracture of the lower extremity of the radius—Colles's, or, as it is more commonly though less correctly called in this city, Barton's fracture—which I had up to that time invariably treated with the forearm in a semi-prone position: indeed, almost the only cases with the result of which I was quite satisfied were those in which there was sufficient impaction of the fragments to

prevent any axial rotation of one upon the other. Hence I resolved to employ the supine position in these, as well as in the cases for which it was originally recommended by Lonsdale; and my experience has been so gratifying that I feel justified in recommending a trial of the plan to my professional brethren.

Axial displacement is no doubt less apt to occur and less marked in fractures through the broad carpal extremity of the radius, than when the shaft of the bone is the part involved; but I believe that it does occur, and that it deserves more consideration than it has commonly received. The muscles which supinate the upper fragment in these cases, as in those of fracture of the radius at a higher point, are the biceps and supinator brevis, which readily overcome the opposing action of the pronator radii teres; the supinator longus, attached to the styloid process of the radius, assists in producing the characteristic deviation of the hand toward the radial side; while the pronator quadratus, often lacerated by the edge of the upper fragment, draws the radius toward the ulna and thus tends to obliterate the interosseous space. What now is the necessary effect of fixing the limb in the semi-prone position, as ordinarily directed? Obviously, the upper fragment which cannot be fully controlled by the splints will be, in some degree at least, thrown into a state of supination by the muscles first mentioned, while the pronator quadratus is given the best opportunity to obliterate the normal space between the bones and thus allow the formation of callus in an undesirable position, the supinator longus, too, exerting a constant force which the surgeon hardly overcomes by using Dupuytren's ulnar splint or one of its numerous modifications.

The adoption of the supine position appears to me to obviate these difficulties; axial deformity is prevented, because both fragments are supinated to the same degree; the interosseous space—small at best in this part of the limb—is not encroached upon, for the position of supination and the even pressure of a well-padded palmar splint prevent the contraction of the pronator quadratus muscle; and the relaxed supinator longus has less tendency to maintain that abduction of the hand which has so often baffled the surgeon's efforts in the management of this injury.

The only objection to the mode of treatment which I have recommended is that, should the case be complicated with a luxation of the lower extremity of the ulna, the position of *extreme* supination would render it more difficult to keep the dislocated bone in place; but this difficulty may be obviated by making the pad which is placed upon the palmar surface of the limb broad enough to press directly upon the projecting ulna, and by limiting the degree of supination to an angle of from 120° to 130° .

With regard to the mode of carrying out the plan which I have advocated, I may say that I have been able to meet every indication by using the customary palmar and dorsal compresses, with either two straight splints or an ordinary "Bond's splint,"

such as is commonly employed in this city. The only point in which my practice differs from that of my neighbors is that I apply the dressings while the injured limb is in a state of supination, and that I keep it supinated during the whole course of treatment. I may add that I have found no objection whatever on the part of patients to maintain the required position, the supinated forearm being comfortably supported during the day in front of the body in a broad handkerchief sling, and extended at night, still supinated, upon a soft pillow.

ON THE TREATMENT OF ULCERS OF THE LEG BY CIRCUMCISION.

BY E. T. BRUEN, M.D.,

Resident Physician, Philadelphia Hospital.

IN the issue of the *Medical Times* for June, 1873, an article appeared, taken from a German journal, stating that chronic, extensive, and otherwise intractable leg-ulcers had been successfully treated by an incision around the circumference of the ulcer down to the deep fascia. If care was taken to prevent union of the cut surfaces, a rapid cure was effected under the use of a simple water-dressing. Two cases were treated in the surgical wards of the Philadelphia Hospital during the past summer; and, thinking that the results might interest some, I shall give their history, as follows. Their perusal will probably indicate why further trial of circumcision was not made.

Charles Garton, æt. 61, admitted to the hospital January 21, 1873. He had a small ulcer situated on the anterior and outer surface of the leg, midway between the ankle and the knee. He was treated with various dressings, but without success, until last June, when it was determined to try circumcision. This was accordingly practised about the 1st of June by my predecessor, with the following results. The tissue included between the line of incision and the ulcer immediately commenced to slough, so that in a few days the ulcer was enlarged about one inch all around; but the mischief did not stop here, for the ulcer continued gradually to spread, in spite of every application which could be suggested. The surface was twice brominized, but, notwithstanding, an abscess formed in the tissues over the ankle-joint, while the man's general health rapidly declined. Another abscess formed in the upper third of the leg, dissecting between the muscles; a third was formed in the calf, and death from septicæmia and exhaustion was feared. Under nourishing diet and suitable treatment, he gradually recovered his usual health; but before the spread of the ulcer was checked it had extended nine inches longitudinally, and five inches, or nearly around the limb, transversely. The surface has been slowly healing for the past eight weeks, and is now almost entirely well; but it occupied three months to restore him to the condition he was in before the trifling operation.

The other case was in a man—Robert McCauley, æt. 60—admitted to the hospital during the month of March, 1873. He had a small ulcer situated in the calf, in the middle third of the leg. He had suffered from it for at least fifteen years, but it had been entirely healed several times during that period. An incision about one and a half inches from the margin of the ulcer was carried around it. The tissue speedily sloughed, and the ulcer gradually increased in depth and extent: finally, an

imperfectly-nourished, callous cicatrix formed over a portion of the surface, and the ulcer remained more intractable than before. After many fruitless attempts to heal it, the man was etherized, and the hardened callous tissue was removed, the entire surface being afterwards cauterized. The resulting ulcer is at present about five inches in diameter, the same extent longitudinally, and is now showing a tendency to cicatrization; but the man states that it is larger than it has ever been previously.

It does not appear to me that cell-change is sufficiently active, nor is the vitality of chronic leg-ulcers of such a character as to justify the danger of enlarging the pathological surface when the morbid conditions can be treated by numerous other measures not open to such objections. The subject is so trite that I should not have ventured to report these cases had I not been aware that the method of treatment has been somewhat discussed. It is proper to add that both these cases seemed favorable for a fair trial of this new mode of treatment, as both men enjoyed excellent health.

October 22, 1873.

CASE OF TWINS CARRIED SIX MONTHS —JAUNDICE, ASCITES, ETC.

BY COMEGYS PAUL, M.D.

ON the 14th of February I was called to see Mrs. M., aged 29. In June, 1872, she was taken with an acute attack of jaundice, which, in a measure, shortly subsided. The yellow color, however, never entirely disappeared, and at different times was of a more decided hue than at others. Her general health in the mean time was apparently moderately good. She menstruated freely, naturally, and with regularity, until the middle of the following August, when the catamenia ceased, and she began shortly afterwards to exhibit signs of pregnancy. After the lapse of four months she felt the quickening of the child, and its movements were very perceptible to her till the second half of the sixth month, when they ceased; a slight secretion of milk entirely disappeared, the breasts became flaccid, and she gave other evidence of carrying a dead fetus. Still she continued to increase in size, and, becoming very much prostrated with attacks of acute pain, her friends became anxious about her, and determined to change their physician, who gave them an unfavorable prognosis, saying she had cancer of the liver.

This is the history so far as I could obtain it from the patient and her husband.

When I saw her in the middle of February my attention was particularly attracted to the bright-yellow color of her complexion, the abdomen enormously distended from ascites, the general anasarca, and the distressed expression of her countenance. Her pulse was 90, strong; her respiration oppressed by the abdominal distention. The day before, she had had a copious epistaxis. Vaginal examination showed an enlarged uterus, but its extent could not be determined, because of the excessive quantity of water surrounding it. The os uteri permitted the introduction of two fingers, but the examination

was otherwise unsatisfactory. The next day, with the assistance of my friend Dr. J. R. F. Bell, I could make out the presence of a child's head, and we decided upon the propriety of inducing labor the following day.

Unfortunately, this delay was fatal to her. That very night she expelled two small children, one alive and the other dead,—apparently for some time,—and, as medical aid was not at hand at the time, she had excessive and fatal hemorrhage. They had neglected to send for a physician until the children were born, and when I arrived she was in a condition alarming in the extreme. The surface was blanched, and her pulse scarcely perceptible, but the hemorrhage had stopped. She was unable to swallow, and exhibited the jactitation so common to similar cases. She was conscious till the end, and died a few minutes after my coming.

Autopsy, nine hours after death.—Body emaciated, but not extremely so. Surface of a very pale yellow. Brain not examined. Lungs and heart healthy, except a slight congestion of the former, due to labored breathing, from their confined thoracic space and the inability of the diaphragm to move because of the upward pressure of ascites. Abdomen enlarged and umbilicus protruded; when opened, about five quarts of a yellowish, viscid fluid flowed out. The *liver* was enlarged and congested, but showed no signs of abscess, nor the dense fibrous appearance due to scirrhus. It seemed more like a simple chronic congestion. The common bile-duct was much reduced in calibre, and the gall-bladder distended. Stomach healthy. The uterus was of the size we would expect at the sixth month of gestation; the tissue flabby and pale; the os was patulous, and the sinuses uncontracted. The kidneys were congested, and the ureters thickened and slightly distended. We had no opportunity to examine the urinary secretion.

PHILADELPHIA, 326 SOUTH SEVENTEENTH STREET.

ON HÆMATURIA.

BY W. D. MARTIN, M.D.,

Pennsylvania Steel Works.

IN vol. iii., on page 66, of the *Medical Times*, I reported a case of hæmaturia, bloody urine being the solitary symptom of the case. It was without pain or uneasiness, apparently without sufficient cause, and at that time, October 15, had continued for ten months in spite of the use of astringents and hæmostatics actively employed. The patient was then placed upon phosphate of iron and the valerianate of zinc, as there mentioned, and continued their use during three months, greatly to the improvement of his general health, but without particular benefit to the hemorrhage, which still continued.

In November he abandoned medicine entirely, and was advised to practise cold ablation of the parts twice every day; and he faithfully followed these directions for more than nine months, or until August, 1873, hæmaturia still persisting. The

gentleman in the interim was in active pursuit of business as before, taking much exercise and enjoying perfect general health.

On August 14, the discharge was apparently worse than ever, being, as he says, "formidable in appearance, and very bloody." Upon rising the next morning, however, the urine was clear, normal in appearance, and without blood; nor did blood subsequently reappear. And thus, being at that time on a visit to the same place (Monroe County, Pennsylvania) where he had acquired the affection, he finally left it there. He now considers himself well.

Referring to the source of this hemorrhage once more, I will observe that it was probably from varicose vessels. I will not attempt to explain the singular manner of its cessation, but will state, finally, that the diuretics and astringents employed in the case probably aggravated it.

October 30, 1873.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY OF PENNSYLVANIA.

SERVICE OF DR. H. C. WOOD,

Clinical Lecturer on Diseases of the Nervous System.

Reported by Dr. LOUIS STARR.

LOCAL CHOREA.

LOUISA —, 15 years of age, first applied for treatment at the dispensary on April 17, 1873. She has a healthy family history, and enjoyed good

health herself until five years ago, when she had scarlet fever. During convalescence from this, she had an inflammatory affection of the right side of her face, probably erysipelas in character, and associated with much swelling, redness, and pain. Shortly after the latter—which lasted two weeks—had subsided, she began to have contractions of the muscles of the left arm and leg, and a feeling of numb-

ness extending over the right side of the body. The muscular contractions were often severe enough to flex the forearm upon the arm, and the leg upon the thigh, and keep them so for a week or more: they occurred, however, only at intervals, and have been entirely absent for the past year. She began to menstruate ten months ago, and since then has been perfectly regular.

When she came under observation, although able to flex and extend the left arm and fingers and pronate and supinate the hand, there was some want of co-ordination, the movements being awkward and constrained, with a tendency to pseudo-chronic spasm, but without any trembling or jerking. When the arm was held out from the body, the fingers were bent backward, and the hand from time to time assumed various positions, according as the flexors or extensors predominated over each other.

She was ordered gr. xx of potass. bromid. three times

daily, with ung. belladon. applied to the arm. This treatment was continued from April 17 to June 12, when it was suspended, and she was directed to take three times daily one-fourth grain of argent. nitrat.

This was continued for some time without avail. Galvanization, both by the descending continuous current and the rapidly interrupted faradaic, was also tried, but did no good; and the patient was finally discharged unbenefited by treatment.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS, M.D.

Reported by J. B. ROBERTS.

OVARIOTOMY FOR THE REMOVAL OF A MULTILOCULAR CYST.

THIS woman, 30 years of age, has suffered for nearly four years with a cystic tumor of the ovary, which has been tapped twice within the past six months, twenty-six quarts of fluid being drawn off at the first operation, and nineteen quarts at the second. The fluid has re-accumulated in large quantity since the last paracentesis, and she now comes to the clinic to have the tumor removed by ovariectomy.

The ovary is subject to various growths, both benign and malignant. Of these the most common is the cyst, which is unilocular or multilocular, and may be filled entirely by serous fluid or contain solid material in addition to the fluid. The diagnosis between these tumors of the ovary and other affections in the same situation is often exceedingly difficult, and there are recorded numerous instances in which the surgeon, after opening the parietes of the abdomen, has found to his dismay that there was no ovarian tumor whatever, but disease of the uterus, liver, or kidney.

Ascites may be mistaken for ovarian dropsy; but there are distinguishing features which will usually render the diagnosis sufficiently clear. In ascites the effused fluid is influenced by the patient's position, gravitating to the posterior part of the abdominal cavity when she is recumbent, and falling to the lower portion as the erect posture is assumed; but in dropsy of the ovary very little effect is produced by these changes. Then, again, the belly in ascites is distended generally, while in cyst of the ovary the effusion is primarily developed to one side of the median line, though it does gradually extend entirely across the abdomen; and, moreover, the cyst as it increases in size rises out of the pelvis and draws the uterus up with it, so that the neck of that organ may be almost beyond the reach of the finger introduced into the vagina. Another point of diagnostic value is the state of the health, which in peritoneal effusion is nearly always bad, since the dropsy is a manifestation of some organic disease. In ovarian trouble, however, the constitution frequently remains unimpaired for a considerable time.

Tumors connected with the liver and spleen, and enlargement of these organs, can be recognized by the fact that they increase from above downwards, and not from below upwards. A most extraordinary case is recorded in which renal cyst, or dropsy of the kidney, was mistaken for ovarian disease, and the woman's abdomen opened for the removal of the supposed cystic tumor of the ovary.

In the treatment of ovarian cysts, tapping is frequently resorted to as a palliative method, in order to lessen, by removal of the fluid, the mechanical inconveniences arising from its presence; but if the operation has been performed once it will usually be required soon again, as in a case where paracentesis was performed nearly sixty times within a year.

Since this woman has been tapped twice already,

and the fluid has so rapidly reaccumulated, it seems proper to attempt the extirpation of the cyst by ovariectomy, which, as the tumor appears to contain no solid matter, shall be performed by the short incision.

It is important to see that the bowels and bladder of the patient are emptied, and that the room is kept well warmed during the operation. An incision two and a half inches in length is then made through the linea alba, extending from the pubes upwards, which opening, if the adhesions are not extensive, will be sufficiently large to admit of the removal of the tumor, especially as its contents will be previously drawn off by the trocar. After the superficial incision has been made, a probe-pointed bistoury is introduced, and the muscular wall of the abdomen laid open, exposing the cyst to view, which proves to be multilocular, and when punctured gives a thick yellowish fluid of the consistency of soft soap.

I now seize the sac and endeavor to draw it out through the incision, rupturing with the finger or dividing with the knife the adhesions holding it to the adjoining viscera. It is firmly adherent to the omentum; and, as the attachment is very vascular, a ligature is placed around it before it is cut.

After the cyst is drawn through the opening, the pedicle by which the tumor is attached to the ovary is divided, having been surrounded by a clamp, in order that there may be no possibility of hemorrhage. After all the blood that has fallen into the abdominal and pelvic cavities has been thoroughly removed by perfectly clean sponges, lest peritonitis or pyæmia be induced, the stump of the pedicle, embraced by the clamp, is brought out at the lower extremity of the incision. The edges of the wound are then brought together by several points of interrupted suture, and four pins passing through the muscles and parietal peritoneum. It is necessary to leave an opening at the lower part of the wound, to insure drainage of the effused fluids, the retention of which might induce septicæmia.

An oiled compress is placed over the wound and held in position by long strips of adhesive plaster, after which a mass of cotton is laid on the abdomen and the patient's body surrounded by a broad bandage of flannel. The bowels will be locked up by opium, and the woman kept perfectly at rest, in a room well warmed and free from draughts of air, with her legs flexed on the pelvis, to relax the muscles and thus prevent tension upon the contents of the abdomen. If effusions of a serous or purulent nature occur, the pelvic cavity must be washed out with tepid water and chlorinated soda or permanganate of potassa by means of a syringe, lest the accumulation of these fluids within the pelvis set up inflammation or induce pyæmia.

TRANSLATIONS.

SYMPTOMATOLOGY OF MYELOGENIC LEUKÆMIA.

THE pathology of leukæmia (Prof. F. Mosler: *Virchow's Archiv*, 1873) has of late been made much richer by the cases observed by Neumann and Waldeyer. In the case of the former a characteristic alteration of the marrow of the bones was observed, and these observations were confirmed by the case of the latter observer, in which there was a diffuse hyperplasia of the marrow. In neither of these cases was it possible during life to note the symptoms more definitely; but within a short time Prof. Mosler has had a case of leukemia under his observation, in which, at the autopsy, he found an affection of the marrow, as if

resulting from purulent osteomyelitis, extending over the entire skeleton, and during the life of the patient symptoms indicative of this disease had been noted by him.

The history of the case was of particular interest, as it would lead to the supposition that the primary disease was not one of the bones, but of the spleen. The patient was a laborer, aged forty-four, who had suffered from intermittent for a long time, followed at last by pains in the left side, where also a tumor had been observed. The leukæmia appears to have started as the result of an injury in the region of the spleen. The patient, in the act of mounting a horse, fell, his left side striking upon the pommel of the saddle. The injury was severe enough to induce an inflammatory condition of the spleen, and this was followed by the leukæmia. At the time he was admitted to the clinic the patient presented a typical case of splenic leukæmia. The splenic tumor filled more than half the abdominal cavity. The lymphatic glands were not involved. A drop of blood when examined under the microscope contained more than one-third white corpuscles. The reaction of the blood was alkaline. The patient presented febrile symptoms of a high grade in connection with pains in the splenic region, pointing to a state of chronic inflammation. One symptom—great tenderness over the sternum, so that the least movement gave rise to intense pain—was noticed by Prof. Mosler for the first time in this case. At first he looked upon this tenderness as a nervous symptom; but later he noticed that great sensibility of the thorax was present at points under which swollen lymphatic glands were situated. This idea was strengthened by the fact that the patient had a cough with expectoration. The autopsy revealed the cause of this condition to be the disease of the bone existing in the sternum. Death took place suddenly, and was caused by a profuse hemorrhage of the stomach, due to follicular ulceration of the mucous membrane of that organ.

In opening the thorax at the post-mortem examination the sternum was broken near the manubrium, and a yellow substance, looking like pus, poured out from the broken surfaces. When the sternum was sawn through, the interior presented a dirty grayish-white hue, and in the body of the bone were found cavities, some of the size of a pea. Towards the lower end was one of the size of an almond, which gave the impression of an abscess in the bone. The cortical portion of the bone was intact over all the cavities. The marrow of a vertebra from the lumbar region, and also that of a femur, presented the same dirty yellow color as that of the sternum. The vessels of the marrow were in some places found crowded with white blood-corpuscles. The external part of the bone and the periosteum were normal. A more accurate examination revealed a hyperplasia of the entire marrow of the bones.

The corpuscles in a state of transition from white to red, described by Neumann, could not be found in the body. The spleen presented the usual characters of leukæmic tumor of that organ: it was very hard, had grown fast to the abdominal walls, and contained numerous spots which had been centres of inflammation. No anomalies were found in the lymphatic glands. The case, then, was one of leukæmia with secondary involvement of the marrow of the bones, and it for the first time demonstrates the existence of certain symptoms during life in myelogenic leukæmia. In this case the disease gave evidence of existence by a marked tenderness over the sternum. The hollow bones, however, during life, gave no symptoms that would induce a suspicion of the disease existing within them.

WILLIAM ASHERIDGE, M.D.

ACTION OF THE MORAL NATURE ON THE PHYSICAL.

UNDER this title, Dr. Cornette (*Annales Médico-Psychologiques*, March, 1873) gives two very interesting cases in which entire loss of hair, with change of voice, resulted from depressing emotions.

The first case was that of a perfectly healthy gardener, forty-five years of age, who, after undergoing considerable mental disquietude, through fear of impending poverty, for several weeks, found his hair suddenly growing white and at the same time falling out.

In a few days his head became almost completely bald, the few hairs which still remained in the form of a circle around the temples and occiput being straight, fine, sparsely scattered, and white as snow. His hair had previously been curly, abundant, and quite black. His beard rapidly became affected in a similar manner, and later the hair had entirely disappeared from all parts of the body.

At the same time, his voice, which before had been strong and full, became quite feeble and low in tone, and his whole appearance was that of a man of seventy-five. His health, however, was perfectly good.

Five years later his condition was nearly the same. He was quite melancholy, and but a few hairs, of a downy nature, remained on his body. His voice was still feeble.

The other case was that of a gentleman, fifty-six years of age, in political life and much harassed by public and domestic anxieties.

One morning on awakening he found a large quantity of hair in his night-cap, and, running his hand through that which remained on his head, it came out by handfuls.

Within a very short time he had lost not only all the hair on his scalp, but also that on the chin, and, finally, on all parts of the body.

After six years this gentleman's condition remained the same. His skin had returned to the smoothness of infancy: one would never believe it had been otherwise.

His general health remained good, but, like the previous case, his voice was nearly lost at first, and even after several years was still quite feeble.

A. VAN HARLINGEN, M.D.

TRAUMATISM IN THE INSANE.

DR. CHRISTIAN (*Annales Médico-Psychologiques*, July, 1873) remarks that it was formerly thought the insane did not suffer from cold, heat, or injuries. Observation, however, has proved this idea an incorrect one.

Some authors have maintained an antagonism between insanity and various diseases, and, on the other hand, that insanity predisposes to other disorders.

Without taking up the subject of the relations of insanity to disease in general, Dr. Christian confines himself to the consideration of traumatism in the insane, and adduces a number of cases of injuries of various kinds in such patients. His conclusions are as follows:

Wounds.—Dr. Christian's observations confirm those of others, to the effect that, whatever the form of their mental affection, traumatic lesions in the insane are easily cured. Sometimes the most grievous wounds heal by first intention.

Burns.—These result as favorably as the foregoing.

Fractures.—Although it has been stated by some that fractures in paralytics are recovered from slowly, yet Dr. Christian's experience leads him to believe that, unless when influenced by accompanying depression, they get well with the usual rapidity.

Bedsore.—Dr. Christian's observations incline him to the conviction that bedsores are no more frequent among the insane than among fever or other patients confined to bed under similar circumstances. Of course such sores are more frequent among paralytics, condemned as they are to a prolonged decubitus, and having incontinence of urine as a usual accompaniment.

Dr. Christian further remarks that many cases might be cited where grave wounds have constituted a critical phenomenon of delirium.

It is concluded that the profound modification which insanity impresses on the organism is not of a nature to cause wounds to take on a bad character.

That state of comparative insensibility to pain often noticed in insane persons, Dr. Christian thinks, is only apparent, and is dependent for the most part on the concentration of the faculties on fixed predominant ideas.

It would be interesting to collect facts relative to the results of surgical operations on the insane; but no materials for that purpose exist as yet.

Finally, it is concluded that, taking into consideration the advantages of fresh air, etc., which many insane asylums present, their patients are cured neither more nor less quickly than other wounded persons.

A. VAN HARLINGEN, M.D.

EXTIRPATION OF THE RECTUM.

THE extirpation of the rectum, with the formation of a musculo-cutaneous perineal flap, according to Hueter (*Deutsch. Zeitschrift f. Chirurgie*) is a method by which the difficulties and dangers incident to the operation as usually performed are avoided. The usual dangers, as enumerated by him, are the following four: hemorrhage from the hemorrhoidal arteries which are necessarily cut, the difficulty of their ligation, possible injury to the peritoneum, and, finally, incontinence of feces.

The first act in the operation consists in the formation of a tongue-shaped flap, with the free convex end looking towards the scrotum, the base being bounded by a line joining the tubera ischii. The sphincter ani must next be separated, and the muscular tissue and mucous membrane of the rectum cut obliquely through at a point one centimetre above the anus, so that the entire ring of the anal opening is contained in the flap, and this is then thrown back. The bleeding vessels having been ligated, the extirpation of the gut is to be proceeded with. The edges of the wound are to be united with sutures,—those in the back part of the wound being first applied,—and the flap is then to be drawn into its old place and fastened by stitches. The after-treatment is made much easier by the fact that the feces traverse the normal canal and do not soil the edges of the wound. This method of operating was tried in two cases: the first patient was a drunkard, who, after the operation, was attacked with delirium tremens and finally died of pneumonia; the second recovered without any bad symptoms, and left his bed two weeks after the operation.

WILLIAM ASHBRIDGE, M.D.

DIVISION OF THE SPINAL CORD IN THE NECK (*Indian Medical Gazette*, September 1, 1873).—N. B. Baillie records the case of a woman who lived for six hours after receiving a blow with a hatchet which cut through the third spinous process and the back part of the fourth cervical vertebra, dividing the spinal cord completely, and penetrating into the body of the vertebra in front of the spinal canal.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 15, 1873.

EDITORIAL.

PROFESSIONAL ADVERTISEMENT.

"WHERE are you going to draw the line?" said a friend to us, after reading our editorial of last week. To such inquiries we now reply, once for all, We do not intend to draw the line at all. That is not our business. A medical journal is not an autocrat, that it should settle what rules are to govern the profession. The line is drawn for us, and drawn sharply, by the Code of Ethics of the American Medical Association.

Though it be not a right of journalism to prescribe rules and make regulations, yet it is in its province to see that they are lived up to. More than this, as the representative of the whole profession, it is the bounden duty of an independent journal, so far as lies within its power, to see that no injustice is done to any portion of the profession,—that all have equal chance in the struggle for existence.

The point we want especially to raise to-day is the injustice of allowing Dr. Sly to covertly advertise or to be advertised because he is connected with some hospital, whilst Dr. Straightforward is hooted at and denounced because, not having the same opportunities, he advertises in a different and more open manner.

To this, when stated broadly as a general principle, we suppose no one will object. General principles hurt no one, and their enunciation usually is as sounding brass and a tinkling cymbal.

It is the application, not the mere dead lash, that makes the smart, but it is the smart, after all, that causes the boy to mind his steps. The lash—the general principle—without the application, he little cares for. Now we propose to make the application; but, before doing it, we want to deny emphatically and finally that any *individual* is being attacked. If any feel the random stroke, he probably deserves it: if so, provided he do not complain, he may comfort himself by the assurance that neither we nor his colleagues know that he has been struck.

The first specific evil of which we propose speaking is a practice of the renowned Pennsylvania Hospital. Day after day there appears in the public press an advertisement not merely stating that the wards are open to the sick, but giving also in full the names and residences of the physicians and surgeons on duty. It is against the continuance of this that on behalf of the general profession we desire to protest.

The first reply to our objection to it will no doubt be, The staff does not do it, the managers do it; the staff is not responsible for the actions of the managers. We acknowledge that there is force in this. Yet we doubt if the force is any better than weakness. Does any one suppose for a minute that if the medical staff of the hospital were officially to state to the board that to have their names and places of residence published in the daily papers was derogatory to their professional dignity and injurious to their professional status,—does any one suppose that if this were done the board of managers would prove such a set of churls as to refuse to modify their public cards? We certainly do not. "Shall not suffer to be," says the Code.

Again, it will be said, Pennsylvania Hospital has advertised in this way from time immemorial.

We cannot see, however, what this has to do with the main issue. Let us not darken counsel with words. The sole question is, "Is, or is not, the publication of the Pennsylvania Hospital's card such an advertisement of the physicians in the daily press as shall redound directly to their personal advantage?" Moreover, it is very possible that a custom harmless in a small community will be a gross injustice in a large one. When there were but fifty thousand people, but thirty thousand possible desirable clients, in our city, a man who held a public medical position was, of necessity, known by almost everybody. But since the multitude has swollen to a million, connection with a public hospital can, in a legitimate manner, only bring a physician before a mere fraction of the people. A stranger in a

village is known in a week of all men; in London he is as a speck floating on the Atlantic.

Hence, as a community increases in size, the advertisement in the public press of a physician, as a man of attainments, becomes of more and more value. Moreover, as the density of population increases, the struggle for existence becomes more and more intense. Advantages which in a small, scattered community may amount to very little, in the dense centre may make the difference between poverty and fortune, success and failure.

It was bad enough when our city was smaller, but to-day it is a hundredfold more unjust, to allow one man's name, under cover of a board of managers, to be placed before the people, and to forbid the appearance of that of another because he has no board of managers behind which to shelter himself.

A stranger comes to the city,—feels ill,—has heard, perhaps, of the Pennsylvania Hospital, for the fame of it is all over the land,—knows not what physician to go to, but remembers to have seen the card of the hospital in the morning paper, and, looking it up, sends for the physician or the surgeon advertised therein.

This is no improbable fancy sketch; but a few weeks ago a very analogous incident came under our notice.

In a certain stratum of society in our city, a "head doctor" of "Pennsylvania Hospital" is almost a medical demigod; and who can tell how many office-visits the holders of these envied positions yearly owe to the advertisement of them, paid for by the contributors of the hospital?

We do not want to be misunderstood. We do not charge the medical staff of the hospital with in any way instigating or being responsible for the practice. It is an old but a very bad custom, far more honored in the breach than in the observance,—a custom which becomes more and more contrary to the spirit of the Code of Ethics,—one which is opening the door for a flood of general medical advertising,—a custom which must be abandoned if our Code of Ethics is to be maintained in its purity.

We do not deny that the practice confers some advantage upon the hospital,—facilitates, perhaps, the admission of patients, and increases the fame of the institution. We do deny that it is in any sense necessary to the hospital. Let the card be put in simply with the position of the hospital and the daily hours at which the staff is in attendance for the purpose of admitting patients, and will any one assert that the sick or the wounded will not be able

to gain admission? Is the fame of the institution so slight that its clientèle would diminish even if it did not advertise at all?

It cannot be. The importance of the practice to the hospital must be very slight. Its value to the staff may be great; it is notorious that a position in the hospital insures success in practice; and who can tell how much of that success is due to this daily advertisement? The harm done to the general profession is, however, also very great, the influence for evil reaching much farther than appears at first sight. But we cannot trace this to-day; our columns are too crowded by other matter. In our next issue we shall attempt to do so, and to show that the only correction for the growing evil is the abandonment of this practice by the Pennsylvania Hospital. Will the medical staff request it of the general board?

IT is some comfort to see that others are worse off than yourself. According to the following, which we extract from an exchange, the Philadelphia Hospital is not, after all, the worst in the world:

"At Benguela, in Angola, says the *Correio do Sul*, the military hospital is in such a state that wolves have entered it in search of human flesh. The *Correio Medico de Lisboa*, commenting on this, says, 'Speaking plainly, our colonies, as regards the hospitals, are for the most part the most perfect examples of carelessness, indifference, and contempt of humanity that can possibly be found.'"

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held October 8, 1873, at 8 o'clock P.M.,

VICE-PRESIDENT DR. H. ST. CLAIR ASH in the chair.

Dr. WASHINGTON L. ATLEE referred to an interesting and unusual case that came under his notice October 5, 1873. The patient was a maiden lady, aged 52 years. At his first interview he found her suffering the most intense agony, particularly in the lumbar region. She had been occupying a sitting position on the edge of a sofa, with her feet on the floor, for several days and nights, not capable of being moved or of lying down. Her breathing was oppressed and frequent, pulse accelerated and small, and the stomach rejected everything as soon as taken. The abdomen was distended much beyond the size of that of a woman at full period of gestation, and was as tight as a drum. There was dulness on percussion everywhere, and fluctuation was sufficiently distinct. Not being able to change her position, Dr. ATLEE could not make the examination more satisfactorily; but in order to relieve her intense suffering and impending danger he immediately tapped her, and drew away thirty pints of fluid resembling spring-water and

uncoagulable by heat or nitric acid. The upper portion of the abdomen sank in after paracentesis, but there still remained a considerable prominence in the hypogastric region.

All the distressing and alarming symptoms subsided with the tapping, and the patient was placed comfortably in bed.

Two days after, Dr. ATLEE made a careful examination of the patient. He could distinctly make out a tumor occupying the whole hypogastric region. It was irregular in shape, more or less elastic at different points, movable *en masse*, and resembled a multilocular ovarian tumor. The pelvis was free, the uterus quite movable independent of the tumor, and the sound was admitted three inches.

The diagnosis was a multilocular ovarian tumor, complicated with a cyst of the broad ligament.

Dr. ATLEE received the following history from her :

Menstruation commenced at the age of seventeen, and continued to be regular up to the age of fifty. At times it was painful, and until twenty years of age it was profuse, sometimes clotted. In the spring of 1864 she was prostrated by severe flooding, which she thinks was induced by family affliction. This tendency to hemorrhage continuing, she came Eastward to seek professional aid. She respectively sought the best medical and surgical advice in Pittsburgh, Newark, and New York, and the uniform opinion was that she had a uterine fibroid tumor with a concealed polypus. A very small polypus finally extruded from the lips of the uterus, which she detected herself, and after its removal the hemorrhage ceased. During this time, in the summer of 1865, she noticed that she began to "bloat," but subsequently by the use of pareira brava the enlargement disappeared through copious discharges of urine. The swelling of the abdomen returned, and gradually continued to increase in spite of treatment. She finally came to Philadelphia, to be treated by certain female electricians who gave her every assurance of a perfect recovery. Her general health was somewhat improved by the treatment, but the local disorder seemed to have been aggravated. For the last six weeks her distress has been great, and for the last three or four days and nights it has been insufferable. It was at this stage of her illness that Dr. ATLEE first saw her.

Dr. ATLEE said that this was the second instance he had met with of a cyst of the broad ligament having been accompanied with such extreme suffering and danger. In the first case, as in this, relief followed immediately after tapping.

These cysts of the broad ligament, in Dr. ATLEE'S opinion, rarely involve the ovary, and frequently are curable by tapping alone, particularly if a large trocar be used. He has seen cases of these peritoneal cysts, after having been tapped, followed by ovarian tumors, but he does not remember to have met with a case similar to the one above reported, of multilocular ovarian tumor and cyst of the broad ligament conjoined.

In this case Dr. ATLEE advised the patient to avoid an operation so long as the ovarian tumor remained quiescent and the peritoneal cyst did not fill.

Dr. HAMILTON said the history of the case just related by Dr. ATLEE was a gratifying one, as it afforded at least a ground for hope that some of the necessarily dangerous and fatal operations resorted to in such affections might be dispensed with. Might not the great improvement after the tapping be ascribed to the removal of tension,—just as we sometimes see, in cases of dropsy attended with almost entire suppression of the secretion of urine, that a few punctures in the lower limbs, by releasing pressure upon the absorbent system and secretory action of the kidneys, are followed by very copious discharges of urine?

Dr. ATLEE, in reply to Dr. HAMILTON, observed that

in all cases of dropsy, whether of the abdomen, the broad ligament, or the ovary, tapping was followed by an increased action of the kidneys for twenty-four or forty-eight hours.

REVIEWS AND BOOK NOTICES.

PROCEEDINGS OF THE TWENTIETH ANNUAL MEETING OF THE MEDICAL SOCIETY OF THE STATE OF NORTH CAROLINA, HELD AT STATESVILLE, MAY, 1873. Pamphlet, pp. 81. Raleigh, Stone & Uzzell, 1873.

The proceedings of State medical societies are usually not very interesting except to those who participate in them; and were it not for the very admirable addresses of Drs. Whitehead and T. F. Wood, and the discussion to which the remarks of the latter gave rise, this pamphlet would form no exception to the general rule. Dr. Wood takes very strong ground in favor of the restorative treatment of disease, and supports his views by arguments which, although they seem to us incontrovertible, are not sufficiently cogent to convince Dr. Satchwell, who appears to retain, notwithstanding the recent advances in therapeutics, the lively faith of the preceding generation in the efficacy of mercury and the lancet in the treatment of acute inflammations. This gentleman reiterates in his remarks the same opinions as he expressed in an essay which he read before the Society at its meeting in 1870, and which were severely criticised by Dr. Anstie in *The Practitioner* for December of the same year. If he has read this review, we are sorry to say he has not profited by it, for not only does he still cling to doctrines the fallacy of which has long since been exposed, but he also weakens whatever force his arguments may have by the contemptuous way in which he refers to those who differ from him: classing them together as Todd, Bennett & Co.,—a firm which is, at all events, composed of many of the most scientific physicians and best practitioners of the day. The discussion on the other side was well sustained by Dr. W. A. B. Norcom, whom the Society subsequently chose its president for the ensuing year. Among the papers read is one in which "A Case of Extra-Uterine Pregnancy of Sixteen Years' Standing" is reported. The details of the case are not so fully given as we could wish, but it appears that sixteen years before the patient came under the reporter's (Dr. R. F. Lewis) notice "she became pregnant, and in the usual time gave birth to a child. Soon afterwards she discovered a lump in her right side about the size of a quart cup; this remained without increasing or diminishing in size until about six months before I [the reporter] saw her; she was sitting by the fire, and for some purpose jumped up hurriedly, when she heard something tear in her side. Soon she discovered that the lump was gone, and in a few weeks noticed that her abdomen was increasing in size." She subsequently gave birth to four or five children,—boys and girls. Her condition was discovered during the operation of tapping, which was rendered necessary by the accumulation of fluid in the abdominal cavity. A liquid resembling pus was drawn off, in which was discovered a large quantity of hair. Subsequently an incision three inches in length was made through the abdominal walls, when three rolls of hair were removed, which, after being washed and thoroughly dried, weighed a fraction over four ounces. Some of the hairs are said to have been six or eight inches long. Upon inserting his finger into the abdominal cavity, Dr. Lewis felt a completely-formed but small child in a perfect state of preservation. The husband of the patient objecting to the removal of the child, the abdomen was emptied of a very thick fluid,

--too thick to pass through the largest canula,—and the edges of the wound were brought together with sutures. Union soon took place. In addition to this paper there is a report on "Retroversion of the Uterus," by Dr. R. L. Payne, of Davidson County, and a paper containing the histories of four unusual cases, contributed by Dr. H. O. Hyatt, of Kingston.

THE PRINCIPLES AND PRACTICE OF MEDICAL JURISPRUDENCE. By ALFRED SWAINE TAYLOR, M.D., Lecturer on Medical Jurisprudence in Guy's Hospital. Second Edition. Philadelphia, Henry C. Lea, 1873.

The goodly volumes before us are the chef-d'œuvre of their author, so well known by his smaller works on poison and in this country especially by the hermaproditic American book which we noticed some time since in our columns. The present treatise consists of two volumes of between seven hundred and eight hundred closely-printed pages, and, as the style adopted is concise, contains sufficient space to exhaust the science of which it treats; and we must say that Dr. Taylor has availed himself to the full of the opportunity offered. The author has in this edition considered more fully the general subject of medical evidence, and added also to other parts of the book, especially to the chapter on Wounds and Personal Injuries. The value of the book has also been enhanced by the introduction of many new references. In concluding the announcement, which ought to be all that the present edition needs to insure its sale, we cannot refrain from expressing a desire that books like the present may be more widely read by the profession: if this were so, we might be spared some of the disgraceful court scenes which have brought so much obloquy upon us. The binding of the work is fairly substantial, and very neat; the typography is of that attractive style which indicates English manufacture. If we mistake not, the publisher has imported sheets rather than reprinted the book,—a most commendable procedure, as it is probable that under such arrangement the author gets his crumbs.

EXPERIMENTAL RESEARCHES ON THE CAUSES AND NATURE OF CATARRHUS ÆSTIVUS. By CHARLES H. BLACKLEY, M.R.C.S. Eng. Small 8vo, pp. vii., 202. London, Baillière, Tindall & Cox, 1873.

Judging from the number of new publications to which it gives a title, periodical catarrh must be upon the increase both in this country and Great Britain; and, as our own observation of the number of cases met with confirms this opinion, we think any attempt to throw light upon the subject is entitled to the attentive consideration of the general practitioner.

Mr. Blackley, like most of those who have written upon this malady, is a sufferer from it himself; and it is to the persistence with which its claims to attention have been urged upon him that we owe the lengthy series of experiments upon its causes which are contained in this little volume.

The observations of other writers upon annual catarrh are first reviewed, and their opinions carefully analyzed, after which the author's own experiments are detailed at some length. Through these details it is unnecessary to follow Mr. Blackley, it being sufficient to say that the amount of the catarrhal symptoms was ever found to correspond closely with the amount of pollen found floating in the atmosphere, as demonstrated by the microscope, and that both reached their highest development in the vicinity of grass-fields during the time of hay-making. Mr. Blackley does not hold, with Bostock and others, that heat and light exert an influence upon the symptoms, but regards pollen, and pollen alone, as the exciting cause, going so far as to propose calling it *pollen catarrh*.

Treatment by drugs is of little avail, the only effect-

ual remedy appearing to be the removal of the patient into a region where vegetation is scanty, to which end some of the British watering-places have been tried and are recommended by Mr. Blackley. Our author does not appear to have seen Dr. Wyman's book upon autumnal catarrh, where the advantages of a residence among the White Mountains are detailed, but speaks of Fire Island as a well-known resort of sufferers from this complaint on this side the Atlantic. Long Beach, opposite Tuckerton, a narrow strip of sand upon the New Jersey coast, has also proved of much benefit to many cases within our own knowledge.

Mr. Blackley, indeed, seems only to know of the summer form of the complaint, while that occurring in the fall is of equal frequency in this country, and the existence of which must lead to a modification of his views, which may be thus stated: in a person predisposed by individual peculiarity, often of a gouty family, almost always in the better walks of life, pollen of various kinds produces an irritation of the mucous membrane of the eyes and the whole respiratory tract of greater or less intensity, which is aggravated by light, heat, and sudden atmospheric changes, and this irritation may vary in degree from a slight and trivial catarrh to a violent bronchitis with the most intense dyspnoea.

In conclusion, Mr. Blackley says that summer catarrh appears to be increasing, and accounts for the fact by the growth of luxury which attends the rapid concentration of the population of the United Kingdom within towns, the growth of the manufacturing at the expense of the agricultural interests.

DISEASES AND INJURIES OF THE EAR. By W. B. DALBY, F.R.C.S., M.B. CANTAB., Aural Surgeon to St. George's Hospital.

This book, of little more than two hundred pages, is divided into eleven short lectures on the more important features of "Diseases and Injuries of the Ear." Among the lectures we would single out the fifth as the best, if called upon to make any distinction; but they are all very good, and contain the substance of the diagnostic and therapeutical knowledge of the day so far as it pertains to otology. The anatomical and physiological facts are but lightly touched upon; we suppose, because the author relies upon a preliminary knowledge on the part of those who constitute the class at St. George's Hospital.

In the fifth lecture, already mentioned, the diagnosis and treatment of non-purulent catarrh of the middle ear are carefully and clearly set forth, and furnish, therefore, a very valuable guide to any one who has to treat a case of this disease.

The subject of aural polypi is very thoroughly treated in the seventh lecture, accompanied by some "beautifully executed drawings, showing the structure of these bodies, by Dr. Whipple." Under this head we notice that Dr. Dalby recommends the use of "fine fishing-gimp" instead of wire in the formation of the snare in Wilde's instrument, and after the removal of the polypus.

Dr. Dalby says, "I am in the habit of using chloroacetic acid on a small camel-hair brush, and apply it very freely. At the same time, care must be taken not to touch any part of the meatus."

Those parts of the book which relate to mastoid diseases, to the obscure nervous affections of the auditory apparatus, both acquired and inherited, and to deaf-mutism, are full of interest; but we think more should be said concerning mastoid disease and its treatment, even at the expense of space which is given to deaf-mutism. So much has been done for the relief of mastoid disease, and it now constitutes so important a part of the aural surgeon's work, that no book on diseases of the ear is complete without a very thorough

review of the diagnosis and treatment of this important and tractable malady, while deaf-mutism hardly falls within the province of the aural surgeon, at least not to the exclusion of more remediable troubles of the ear.

The great importance of chronic discharge from the ear is acknowledged and most forcibly enjoined in the following words, which close the eighth chapter:

"But inattention to the discharge may at any time place the patient in a position of great peril. For this reason I believe that a discharge from the ear is regarded by insurance companies as an element against granting a policy, or, at any rate, demanding an increased premium. I can only say that, if it is not so regarded, it would be, if the companies consulted their own interests."

We can but terminate this short sketch by saying that the perusal of this book has been not only instructive but extremely pleasurable, and we are glad to acknowledge the addition of such a volume to the literature pertaining to otology. C. H. B.

GLEANINGS FROM OUR EXCHANGES.

HOW COLD-BLOODED ANIMALS ARE AFFECTED BY LOW TEMPERATURES.—Dr. Dönnhoff has been making some experiments on this subject, which he describes in *Reichert's Archiv*. He put bees, spiders, and flies on the frozen ground in his garden, under wire covers, the temperature on the ground being $-1\frac{1}{2}^{\circ}$ C. The bees were soon apparently dead, the others still moved after five hours. All were then brought into a warm room. The bees did not revive, but the spiders and flies were in a few seconds lively again. On other days the thermometer stood at -3° . The spiders soon ceased to move, while the flies weakly moved their feet the whole time of exposure, eight hours. In the warm room it was found that the spiders were dead; the flies soon flew about. Next evening, at eight, the thermometer showing $-3\frac{3}{4}^{\circ}$, flies were put in the garden; at eight the following morning the thermometer stood at $-6\frac{1}{2}^{\circ}$; the flies were apparently dead, but when brought into the room soon revived.

A few days afterwards, the flies were put in a small glass, $1\frac{1}{2}$ inches long and half an inch broad. This was sealed and put in a freezing-mixture of snow and salt, the thermometer in which showed at first $-6\frac{1}{2}^{\circ}$, and after four hours $-3\frac{1}{2}^{\circ}$. The flies kept in the glass all this time were brought into the room, and soon flew about. They were next subjected to a freezing-mixture of -10° , the thermometer in three hours showing -6° ; but this killed them.

Leeches were placed in a temperature of $-1\frac{1}{2}^{\circ}$. In an hour they were frozen stiff (but not hard), like pieces of meat which were put beside them. The water in the animals was not all frozen, a concentrated solution (according to physical laws) remaining liquid. If the leeches were cut through with scissors, the section appeared whitish, from ice. Brought into the room, the animals moved about after a quarter of an hour, and, when seized, balled themselves like healthy leeches. Other leeches, kept three hours in a temperature of $-1\frac{1}{2}^{\circ}$, afterwards revived, but could no longer crawl, and died in a few days. Leeches kept a few minutes in a cold mixture at $-6\frac{1}{2}^{\circ}$ were dead.

Silkworm eggs were exposed on the frozen ground twenty-four hours, the temperature varying from -2° to 1° ; others to a temperature varying from 4° to $-2\frac{1}{2}^{\circ}$; others to one varying from $7\frac{1}{2}^{\circ}$ to 6° ; others were placed in a small glass, and this in a freezing-mixture of -21° , in which they remained five hours, the thermometer at the end of this time showing -15° . The half of each por-

tion of eggs Dr. D. put in small linen-covered flasks, and the flasks in a bag which he carried on his breast during the day, and took into bed with him at night. In a few weeks active worms came out of all the eggs. The other portion of the eggs he had placed in a warm room; some weeks later, worms came out of these also.

These experiments show that cold-blooded animals behave like plants with regard to freezing temperatures. They die like these at different freezing temperatures. The honey-bee dies at -1° ; the spider at -3° ; the flesh-fly survives a temperature of -6° ; the silkworm egg one of -21° . And as there are plants in which the water may be frozen without their dying, there are some animals in which this occurs. In leeches a part of the contained water may be frozen; the silkworm egg may be frozen solid, without life being extinguished.

In the spiders and flies exposed to freezing temperature a part of the water was frozen; but, as contraction of the muscles still took place in a temperature at which pieces of meat were frozen stiff, it is improbable that their muscles were frozen. The freezing of the water in leeches puts an end to all motion. They move at 0° , but at $-1\frac{1}{2}^{\circ}$ are quite still.—*Boston Journal of Chemistry*.

ON INFLAMMATION OF THE THORACIC DUCT.—Dr. Chouppe, of Paris, has just published a thesis in which he has collected five cases of the above rare and, as yet, not well-known affection. The five cases collected by Dr. Chouppe are the only ones hitherto placed on record. In three of the cases the inflammation was secondary, and in two primary. In order to distinguish this latter form from the former, Dr. Chouppe has conducted a series of experiments on animals. The points brought out by the two cases and by the author's experiments are very interesting. In both cases the inflamed thoracic duct had thrown a quantity of pus into the general circulation through the subclavian vein, and it might be said that the patients had had a sort of pyæmia through an internal course; yet, during life, typhoid fever, meningitis, and articular rheumatism were successively suspected, whilst purulent infection was not even thought of. Another point of interest was the obliteration of the subclavian vein in one of the cases; it could only, however, have occurred during a late period of the disease, as symptoms of pus in the blood had been previously observed. Notwithstanding the great importance of the thoracic canal, as conveying all the chyle produced by digestion, and the most part of lymph, no disturbance in the digestive organs or in the functions of nutrition was observed. Moreover, Dr. Chouppe stated the existence of pulmonary infarctus, caused, according to him, by the pus producing embolisms. The other symptoms were redness of the surface in various parts, inflammation of the sheaths of tendons, and of several joints. In both primary cases the onset of the disease was sudden: in one case it came on with violent pain in the stomach and intense fear; in the other, with a violent and protracted fit of rigor. In the two cases these symptoms were followed by high fever, prostration, loss of strength and flesh.

Dr. Chouppe has arrived at the following conclusions on the important questions which he has investigated: Primary inflammation of the thoracic duct does exist; it is attended by general symptoms of purulent infection and by local symptoms; it cannot be diagnosed as yet during life by the help of known symptoms, but its presence may be suspected; it is likely that it has been sometimes overlooked, and that it occurs occasionally.—*Medical Times (Canada)*.

SCLERODERMA.—Dr. Arthur Van Harlingen, in a concise and well-written paper upon this subject, in the *American Journal of Syphilography and Derma-*

tology, October, 1873, relates a case which came under his observation, and also makes an analysis of scleroderma in general. The object of the communication is to point out the clinical features of the disease and to show its distinctive character in opposition to those views which would connect it with other affections of a more or less similar character.

The following definition is proposed:

"Scleroderma is an affection of the skin, characterized by diffused symmetrical hardening, and generally accompanied by more or less pigmentation. Beginning in some particular locality, without febrile disturbance, swelling, or œdema, the induration spreads with greater or less rapidity over a considerable extent of surface. The affected parts fade gradually into those which remain healthy, without any distinct line of demarcation, and they are on a level with the general surface, neither raised nor depressed, and contain no tubercles or other elevations. The temperature of the affected surface is either normal or slightly depressed. The general sensibility, as well as the functions of the glands, are unaffected, save in the advanced stages of the most severe cases. It runs a chronic course, uninfluenced, or nearly so, by therapeutical applications, and has no tendency to a fatal termination.

"Pathologically, the disease consists essentially in a great increase in the fibrous elements of the corium and papillary layer, decrease of fat in the subcutaneous connective tissue, and deposit of pigment in the lower layers of the epidermis and in the rete."

This definition, Dr. Van Harlingen holds, will exclude the well-known case of Rasmussen, which has been frequently quoted as one of scleroderma, but which, it is maintained, is wanting in most of the characteristic features of scleroderma.

Scleroderma and the keloid of Addison are separated and considered as entirely distinct diseases.

SHOCK AND SYNCOPE (*The Practitioner*, October, 1873).—Dr. T. Lauder-Brunton, in an able paper, reviews the causes, symptoms, pathology, and treatment of shock and syncope. He believes painful impressions,—more especially extensive burns,—injuries to bones, and, above all, injuries to the abdominal viscera and genitals, to be the principal causes of shock, which is usually attended with pallor and coldness of the skin, weak pulse, oppressed and sighing respiration, dilated pupils, and sickness. There are two chief factors in the production of shock: first, the stoppage of the heart from the paralyzing influence of a sudden and violent injury to the nerves, and second, as a result of the same influence, dilatation of the vessels, particularly those of the abdomen. These two enable us to account for all the observed symptoms,—the weak pulse, the low arterial tension, the pallor and coldness of the surface, etc.

Syncope probably depends chiefly on dilatation of the arterioles, and its duration is less than that of shock, because of the greater contractility of these vessels than of the veins.

In the treatment of shock we endeavor to counteract the feebleness of the heart by stimulants,—one of the most powerful of which is heat: so we apply warmth to the surface, especially over the cardiac region, and at the same time give brandy and other internally. A still more important indication is to cause contraction of the great veins in the abdominal and thoracic cavities, so that the blood, instead of stagnating uselessly in them, may be sent onward to the heart. Painful impressions on the sensory nerves will often have this effect,—strong mustard plasters, thrashing the feet and legs with switches, etc. Digitalis, as possessing the power of contracting the vessels and strengthening the pulsations of the heart, is of great value, and should be

given freely. In syncope the first idea is to restore the circulation to the brain; and this we do by laying the head on a level with the body or even somewhat lower. The next thing is to raise the blood-pressure; and, as the condition is due to dilatation of the arterioles of the surface, we pursue a plan of treatment directly opposite to that employed in shock, and dash cold water in the face and chest and hurry the patient from a warm room into the cold air, in order to cause contraction of those vessels. For the same reason we apply ammonia or aromatic vinegar to the nose.

TREATMENT OF ORCHITIS WITH NITRATE OF SILVER (*Pacific Medical and Surgical Journal*, October, 1873).

—Dr. W. E. Whitehead states that his plan of treatment for orchitis has been as follows. Rest in bed, and the application of a thorough coating of a solution of nitrate of silver—forty to eighty grains to the ounce—to the scrotum of the affected side, first having the scrotum well washed in soap and water; the administration of small doses of Epsom salts and tartar emetic dissolved in water, and repeated as often as once in four hours; support to the testicles, and low diet. In some cases it is only necessary to make one, or at most two, applications of the solution of nitrate of silver to the scrotum; but sometimes it becomes necessary to paint once a day for three or four days before the swelling and pain are arrested. When the whole testicle is painful, hot, and swollen, stretch the scrotum over it gently, and then apply the solution with a camel's-hair brush; but when the testicle is not so seriously implicated, merely draw the scrotum lightly over the epididymis portion, and apply the solution in the same way. One application is generally sufficient to relieve the extreme pain and at once arrest the inflammation and distressing sense of tension in the testicle, and the lumbar pain that follows the course of the spermatic cord. When the inflammation runs high, give tartar emetic in nauseating doses, otherwise in much smaller quantities.

POST-MORTEM NOTES ON THREE CASES OF HANGING (*Indian Medical Gazette*, September 1, 1873).—G. G. MacLaren, M.B., had the opportunity of making post-mortem examinations on the bodies of three criminals who had suffered death from hanging. In none was there any emission of semen or feces. In two there was great congestion of the brain, attended in one case with effusion into both lateral ventricles. In the other there was little congestion, but some sub-arachnoid effusion. The lungs were collapsed and anæmic, the heart normal, and the pericardium partially filled with fluid in all three cases. In one there were dislocation between atlas and axis, and rupture of the odontoid ligaments; in another, dislocation and rupture of ligaments between the axis and third cervical vertebra; and, in the third, dislocation between the atlas and the occipital bone.

In two cases reflex movements were noticed for a few minutes after the drop fell, but in the third case not a single movement could be detected.

THE DETECTION OF ORGANIC MATTERS IN THE AIR.—At the Chemical Society of Berlin, Prof. Smee proposed a method for discovering the organic matters contained in the air by means of distillation by cold. A glass funnel, with the tubes stopped, is filled with ice and held suspended in the air. The humidity of the air is condensed upon the outside of the funnel along whose surface it trickles, to drop in a little basin beneath. This liquid is weighed. It contains ammonia, usually, which is separated and its quantity determined by well-known methods. The quantity of organic matter in the air is then approximately estimated by that in the liquid. It is possible in this way also to arrive at the odorous principle in flowers.—*The Druggist*, August, 1873.

A NEW REACTION OF ALCOHOL (*Le Progrès Médical*, August 23, 1873).—The discovery of alcohol in organic liquids is often of great difficulty, owing to the small quantity of liquid which the chemist has at his disposal, and the absence of any distinguishing test. We owe to M. Bertholet an obvious and characteristic reaction.

In the presence of cold or lukewarm water benzoic chloride ($C_{14}H_5ClO_2$) is only decomposed with extreme slowness, but, on adding alcohol to the liquid, benzoic ether is immediately formed, and is thrown down in excess. The presence of this ether becomes apparent if a few drops of the liquor are heated with a solution of caustic potash; the chloride only is decomposed, while the ether remains unaffected. This reaction is very evident with a liquid containing one per cent. of alcohol, and allows us to dispense with distillation.

EVACUATION OF A PORTION OF BOWEL.—The following case occurred in the wards of Dr. Demarquay, at the Hospice Municipal. A boy of fifteen was taken with a violent fit of vomiting, colic, and diarrhoea, after eating some sugar-plums painted in red, green, and blue. The stomach was tense and swollen, and six worms, together with three bits of a fleshy substance, like boiled liver, were thrown up. Twenty other worms were afterwards successively vomited. On the fifteenth day the patient evacuated a piece of thickish, slimy membrane, about an inch broad and twenty inches long, and into which the finger could be introduced like a glove. After this the boy went on lingering, with frequent attacks of diarrhoea, and, though the appetite was good, he gradually lost flesh. The attacks were doubtless occasioned by the fecal mass reaching the retracted portion of the soldered bowel. The patient died, but a post-mortem was not allowed to be performed. *London Lancet*.

MISCELLANY.

WHAT ARE INSTINCTIVE ACTIONS?—This is really, to the thoughtful man who is learned on the subject, a most intensely difficult question. A paper on this subject appears from the pen of Mr. George Henry Lewes, in *Nature*, and is well worthy of perusal. The author states, among other things, that the fact that we require some character to distinguish the instinctive from the impulsive actions may be readily shown. No one calls breathing, secretion, excretion, etc., instincts. Yet these are the actions of congenital tendencies in the organism. "A hungry chick," says Mr. Spalding, "that never tasted food, is able, on seeing a fly or spider for the first time, to bring into action muscles that never were so exercised before, and to perform a series of delicately adjusted movements that end in the capture of the insect." Every one would pronounce this a typical case of instinct. Now compare with it the following, which no one would class among the instincts: A newborn animal that has never breathed before is able, on first feeling the stimulus of the atmosphere, to bring into action a very complicated group of muscles which were never so exercised before, and to perform a series of delicately adjusted movements which end in the aeration and circulation of the blood. This contrast may lead us to the character sought. Understanding that every line of demarcation in psychical phenomena must be more or less arbitrary, and only justified by its con-

venience, we may draw such a line between impulse and instinct. Impulses are the actions which from the first were fatal, inevitable, being simply the direct reflex of the stimulated organs. Given the respiratory organs and the atmosphere, respiration is the inevitable result. Given the secretory organ and the plasma, secretion is the inevitable result. There is no choice: the action either takes place, or it does not.—*The Lens*.

DESTRUCTION OF LIFE IN INDIA.—The numbers of people destroyed by wild beasts constitute an extraordinary feature of Indian life. The loss of life is very great in some districts, and in others it is less only because goats are abundant, and the wolves prefer kids when they can get them. No fewer than 14,529 persons lost their lives by snake-bites in 1869, and in 1871 there were 18,078 deaths reported as caused by dangerous animals of all classes; but Dr. Fayrer is of opinion that systematic returns would show that there are more than 20,000 deaths annually from snake-bites. The inhabitants of the border-lands between jungle and cultivation are killed and eaten by tigers in such numbers as to require the serious attention of the government. In Lower Bengal alone 13,401 human beings were killed by wild beasts in six years, and 40 in South Canara in the single month of July, 1867. The chief commissioner of the Central Provinces has to report 946 persons killed by tigers in three years ending with 1869. There are difficulties in the way of extirpating tigers: the natives regard the man-eating tiger as a kind of incarnate and spiteful divinity, whom it is dangerous to offend, and it is the desire of a few in India actually to preserve tigers for sport. Mr. Frank Buckland has suggested an organized destruction of the tiger-cubs in the breeding-season, and the attraction of full-grown tigers to traps by means of valerian, of which these animals, like cats, are exceedingly fond.—*British Medical Journal*.

CINCHONA IN INDIA.—A parliamentary paper on the progress of India in 1872 gives information respecting the cultivation of the cinchona-plant, which was introduced into the hill districts in 1860. The total expenditure of the experiment was £61,719. There are now 2,639,285 plants in the government plantations on the Neilgherry Hills alone, without counting those of private planters in this and other districts. The largest trees are 30½ feet high, and over three feet in girth round the trunk. The area covered by the plantations amounts to 950 acres, and is being largely added to every year. The bark under cultivation is stated to be much richer in quinine and other alkaloids than the wild bark of South America. During last year 7295 pounds of excellent bark were sold in the London market, while 65,688 pounds were supplied to the local manufactory. This year 20,000 pounds will be sent home. The alkaloid is manufactured on the spot in an exceedingly cheap form for the use of local medical stores, and hundreds of fever-patients are thus annually cured. The object of providing an abundant supply of the febrifuge at a price within the means of the popula-

tion at large is rapidly being realized.—*British Medical Journal*.

NÉLATON.—The *London Lancet* says, "Authors have not sufficiently insisted on the peculiar timidity and shyness which characterized his general demeanor, so much so that those who might have feared him as a competitor relied on this retiring disposition, and apprehended no rivalry, especially as he was known to have considerable property. But his success with Garibaldi and the favor of the Emperor worked wonders. It is a pity that the circumstance which gained him the Imperial Court drove a colleague of his into an asylum for the insane. Jobert (de Lamballe) had for some time secured the confidence of the Emperor, when the Empress and her suite met with a carriage-accident in Switzerland. The telegram sent to Paris said, 'Let Jobert start at once, or, in his absence, Nélaton.' Unfortunately for the former, he was out of town, and Nélaton went down to Switzerland. His services and his manner won the Empress; poor Jobert was supplanted, and he took the change to heart in such a manner that his mind became unhinged. Nélaton from that period rose with wonderful rapidity. He attended some time afterwards the Czar's son at Nice, his honorarium on that occasion amounting to £16,000."

A DANGEROUS OFFENDER IN CUSTODY.—A man named J. Ryan was arrested in New York, September 27, by Deputy Marshal Crowley, charged with sending obscene literature through the mails. He waived an examination and gave bail in \$5000 to await the action of the grand jury. Ryan has been known by the following aliases: Clinton Medical and Surgical Institute, Dr. John Harvey, Dr. Bell, and Prof. Draper, all of No. 147 East Fifteenth Street; Lucille Demarre, and Lucille Demarre & Co., and Edgar Tremaine, of Station D; Martin Dutton & Co., Nos. 704, 708, 735, 767, and 776 Broadway, and also various numbers in Nassau Street; Marcus L. Bryan, No. 64 Cedar Street; J. Bryan, M.D., of No. 84 Cedar Street; Dr. J. Bryan, No. 96 East Thirteenth Street; Clinton Medical and Surgical Institute, No. 249 South Tenth Street, Philadelphia, and a place in Baltimore. The great sawdust and swindling firm named W. T. Mason & Co., of No. 182 Fulton Street, is also run by Ryan. It is expected that the case will go before the grand jury at an early date.—*Medical and Surgical Reporter*.

FRESH MEAT FROM AUSTRALIA.—The Melbourne correspondent of the *Times* writes that Mr. T. S. Mort, aided by Mr. Nicolle, of the ice-works, has succeeded, after years of unremitting labor and costly experimenting, in discovering a cheap and safe means of applying cold to all perishable articles of food, and is now making great preparations for freezing meat for shipment, and keeping it frozen during the voyage to England. The cattle are to be slaughtered and the carcasses frozen at Bowenfells, on the other side of the Blue Mountains, about a hundred miles from Sydney. By railway they will be conveyed in trucks adapted to the traffic to the depot in Sydney. The depot, which

is a building within a building for the sake of isolating the interior or cold chamber, is capable of holding one thousand tons of frozen meat, and is to contain machinery calculated to produce cold equivalent to sixty tons of ice every twenty-four hours. The agent employed in the production of cold on land is ammonia, and Messrs. Nicolle and Mort have erected extensive works in connection with the gas-works for its manufacture.—*British Medical Journal*.

VEHICLE FOR THE ADMINISTRATION OF CHLOROFORM.—A French medical journal remarks that the best course is to dissolve the chloroform in glycerin (1:3), which is effected with tolerable facility, and gives a very clear solution, pleasant to the taste, and with a strong odor of chloroform. This solution can be mixed in all proportions with water, without the occurrence of any precipitation, though the odor is distinctly perceptible. In forming the mixture, it is well to add the chloroform slowly and to mingle the two thoroughly. It should be left at rest for twenty-four hours; at the expiration of this period a portion of the chloroform will be found to have collected at the bottom of the vase; this should be separated and mixed with an additional part of glycerin, when no further separation will occur. This mixture may be kept for some time without any loss of chloroform by evaporation.—*Boston Journal of Chemistry*.

MUTTON or beef suet can be thoroughly purified by the process of M. Auguste Bermond, of Nice, as follows:

Take twenty-five pounds of perfectly fresh suet, and cut into small pieces, and pound it well in a mortar; after it is well crushed, wash it with cold water repeatedly, so long as the washings are not clear. Then melt over a slow fire, and add about one ounce powdered alum, and two ounces common salt, and let them come to a boil for a few seconds; then strain through a fine cloth into a deep pan, and let it stand for about two hours to allow the impurities to settle; which separate, and put the clean grease into the pan, and add to it one quart rose-water and one and a half ounces of powdered gum benzoin; then heat it gently and remove the scum as long as any arises. Finally, put into a pan and let cool, when the purified suet may be taken off the sedimentary water.

Thus purified, it will keep for an indefinite period without change or turning rancid.—*The Druggist*.

JOHN AUBREY, who was at Harvey's funeral and "helped to carry him into the vault," writes, "I have heard him [Harvey] say, that after his book of the Circulation of the Blood came out, he fell mightily in his practice, and 'twas believed by the vulgar that he was crack-brained; and all the physicians were against his opinion and enoied him. All his profession would allow him to be an excellent anatomist, but I never heard of any that admired his therapeutique way. I knew several practitioners in this town [London] that would not have given 3*d*. for one of his bills [prescriptions], and that a man could hardly tell by one of his bills what he did aime at."

THE BLIND IN PRUSSIA.—From official inquiries, it appears that in the year 1871 there were in the Prussian dominions 22,143 blind persons, or 89 blind persons in each 100,000 of the population. The highest numbers were in the provinces of Posen and Prussia, where there were respectively 107 and 106 blind per 100,000; the lowest number, 7, was found in Hohenzollern. These remarkable differences appear not to depend alone on the geographical position of the several provinces; for Pomerania shows a smaller proportion than any of the southern provinces except Hohenzollern. The number of blind in proportion to the population has greatly increased in the last ten years: in 1859 there was one blind person in 1649 of the population, while in 1871 there was one in 1111. In the sixteen institutions for the blind in Prussia there were only 549 pupils.—*British Medical Journal*.

ELECTRIC LIGHT.—A company in Paris are now making an improved electrical machine for producing the electric light. It is provided with four plates, and when made to revolve three hundred and fifty times per minute affords a light equal to two hundred and thirty or three hundred gas-burners. A steam-engine of two and a half horse-power serves to run the machine, which costs the nice little sum of 8000 francs (\$1600 gold). This is not so very expensive, when we remember that a few pounds of charcoal will produce as brilliant an effect as could be had from twenty pounds of rape-seed oil. The light is well adapted to light-houses, ships, and large halls; and why not for lighting city streets? A few of these scattered about the city would greatly relieve the dangers attendant upon a gas strike.—*Journal of Applied Chemistry*.

LYING-IN-HOSPITAL AT JERUSALEM.—This hospital, established by the Baroness B. de Rothschild, is doing excellent work. Dr. Loudon, the director of the institution, lately issued a report, from which we find that 120 females were received at the hospital during the past year; 48 of these were born in Jerusalem, 24 were Russian born, and 19 came from various parts of Turkey. Each inmate on leaving receives a donation of ten francs, and clothing for herself and child. The early period at which marriage is celebrated in Palestine is shown by the fact that two of the mothers were only fifteen years of age; three had reached sixteen years; five, seventeen years; nine, eighteen years; four, nineteen years; and fifteen had reached their twentieth year.—*Lancet*.

PRESENCE OF ALCOHOL IN THE HUMAN URINE.—After having shown that urine on putrefying produces alcohol, M. Béchamp has sought to discover alcohol in the urine of persons who have previously been subjected to a régime of abstinence from wine and alcoholic drinks. In the urine collected in these conditions, and in which fermentation had been prevented by the addition of a little creosote, M. Béchamp has found enough alcohol to be able to set it on fire. In one of the experiments there was enough alcohol in two litres of urine to be determined by the alcoholometer. The

author believes that the liver produces alcohol physiologically.—*New York Med. Record*. (This is confirmatory of the researches of our countryman Dr. Ford, who years ago obtained alcohol from the blood of animals which had lived lives of strict teetotalism.—ED. P. M. T.)

IN a rather scarce book, called "Mems., Maxims, and Memoirs, by William Wadd, Esq., F.L.S., Surgeon Extraordinary to the King. London, 1827," I find, on page 21, the following note or memorandum:

"Mr. Paul, a surgeon at Stroud, in Gloucestershire, lately extracted from the kidneys of a woman, by an incision through her back, a rough stone as large as a pigeon's egg, and made an entire cure: it is the first of the kind ever performed in this kingdom."—*New York Med. Rec.*, from *Gentleman's Magazine* for Aug. 1733.

AN EXPERIMENT WITH SAFRANIN.—Safranin is now often employed to impart to silk a rose-red color. If a few particles of the pure dye are placed in a porcelain dish, and one or two drops of concentrated sulphuric acid allowed to fall upon it, and stirred with a glass rod, a most beautiful blue color is produced. On adding a drop or two of water it changes to a brilliant emerald-green. By alternately adding a drop of acid or of water, nearly all the colors of the rainbow may be produced.—*Journal of Applied Chemistry*.

THE entries at the German universities for the year 1873-4 are 7467; 3904 being for the winter, and 3563 for the summer session. The number of medical students is 2479. The total number is 851 less than the previous year, when it was 8318, there being a falling off of 444 in the medical entries alone.

DR. STELLWAG VON CARION, the eminent ophthalmologist, has been appointed to the additional professorship of Clinical Ophthalmic Surgery, instituted in the University of Vienna.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 28, 1873, TO NOVEMBER 10, 1873, INCLUSIVE.

MCPARLIN, T. A., SURGEON.—Assigned to duty at Fort Leavenworth, Kansas, as Post-Surgeon. S. O. 169, Department of the Missouri, October 31, 1873.

GHISELIN, JAMES T., SURGEON.—So much of S. O. 206, October 15, 1873, as relates to Surgeon Ghiselin, is revoked. S. O. 217, War Department, A. G. O., November 3, 1873.

MCCLELLAN, ELY, ASSISTANT-SURGEON.—Relieved from duty at Headquarters Department of the South, and to return to his proper station, Lebanon, Kentucky. S. O. 189, Department of the South, October 31, 1873.

WOLVERTON, W. D., ASSISTANT-SURGEON.—Leave of absence extended thirty days. S. O. 219, War Department, A. G. O., November 5, 1873.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Assigned to duty at Camp Harney, Oregon. S. O. 146, Department of the Columbia, October 17, 1873.

WATERS, W. E., ASSISTANT-SURGEON.—Relieved from duty at Fort Leavenworth, Kansas, and assigned to duty at Fort Riley, Kansas, as Post-Surgeon. S. O. 169, Department of the Missouri, October 31, 1873.

KIMBALL, J. P., ASSISTANT-SURGEON.—Leave of absence extended thirty days. S. O. 99, Headquarters Military Division of the Missouri, November 5, 1873.

SATURDAY, NOVEMBER 22, 1873.

ORIGINAL COMMUNICATIONS.

CASE OF EXTRA-UTERINE PREGNANCY —A FŒTUS OF TEN WEEKS EXPELLED PER RECTUM—RECOVERY.

BY H. E. WOODBURY, M.D.

*Read before the Medical Society of the Alumni of Georgetown College,
November 3, 1873.*

EXTRA-UTERINE foetation is of rare occurrence, and this fact gives to the cases met with in practice a peculiar interest. Of all the phenomena incident to generation, no one, it strikes us, is more anomalous or remarkable than this. We can readily conceive how, after impregnation, the ovum may be arrested in its journey towards the womb, its natural receptacle; but why it should become attached to other structures, and from unnatural sources derive nourishment and support, even to full maturity,—as happens in some cases,—this we confess puzzles us. It would be far more reasonable to suppose that, failing to reach the womb, development of the germ would be arrested, decomposition follow, and the blighted product in time find its exit through a natural channel,—the Fallopian tube,—or, failing in this, be removed by absorption. Such, experience teaches us, is not the case; and the greater the pity it were not.

Mrs. J., aged 30, has been married eleven years. A few months after her marriage she had a miscarriage. From that time up to March 13, 1873, menstruation was regular. She had never been pregnant. In April her catamenia did not appear, and she suffered from great pain in the left side, nausea, and general malaise. These symptoms were more marked when her next period returned in May. In June, as she was going downstairs, she was suddenly seized with cramps and bearing-down pains. To use her own expression, "I felt as if everything in me was going to be forced out." She was at once placed in bed, and the nearest physician summoned. He prescribed an anodyne, and left. In a few days she was up again. Soon after, she noticed that some shred-like substances passed from the vagina, and sent for her physician. He prescribed for her, told her she would soon be better, left, and did not see her again.

July 10, 1873, her husband desired me to see her, as she was getting worse. I called, and she informed me that the physician who had been treating her had abandoned the case, and she must have relief, if possible.

Her condition at this date (July 10) was as follows: Pulse 90; tongue heavily coated; bowels alternately constipated and relaxed; extremities cold; fever, insomnia, anorexia, nausea,—all characterized her case. She complained of much pain and soreness in the left lumbar region, and at times there seemed to be an unusual prominence in that part. So great was the tenderness, when this prominence was most marked, that she could not bear the slightest pressure of the hand upon it. From this point as a centre, the pain extended to her back, her breast, her limbs,—in short, over her whole body. Her complexion was sallow, and, at times, almost jaundiced. Her decubitus was dorsal; she could not lie on her left side at all.

My first consideration was, What have I to treat here? Is it a miscarriage, ovaritis, peritonitis, cancer, or extra-uterine pregnancy? My second was,

How shall I determine? I directed that if anything passed from the vagina it should be placed in alcohol provided for the purpose. I ordered turpentine stupes to the abdomen and breast, an air cushion to relieve the back and prevent bedsores, and, as she had lost much sleep, and her stomach was very irritable, I administered, hypodermically, one-fourth grain of morphia at night. Beef-tea, milk punch, and wine were freely given. Lime-water, solution of carbolic acid, and champagne gave her only temporary relief from the vomiting.

As there was a slight discharge from the vagina, I determined as soon as possible to make an examination with the speculum. I began to suspect malignant disease of the uterus. The extreme sensitiveness of the parts had first to be overcome. Tepid enemata of flax-seed tea, with laudanum, soon removed this. The examination did not confirm my suspicions. The cervix was a little larger than normal, and very sensitive, admitting the sound for three-fourths of an inch. Made no effort to pass the instrument into the cavity, and detected no signs of cancer.

July 20.—I determined to try liquor of ergot, as a digital examination convinced me that the womb was about twice as large as it would be in an unimpregnated condition, and I concluded that, if it contained a dead foetus, the sooner it was removed the better. Shortly after its administration she passed from the vagina, at three different times, masses of a shred-like substance, which were at once placed in alcohol. Dr. J. J. Woodward, of the U.S.A. Medical Museum, and his assistant, Dr. E. M. Schaeffer (both of whom manifested much interest in the case), carefully examined these under the microscope. They could detect no indications of malignant disease of the uterus, nor evidence that the substance was the product of an abortion.

A careful examination of the abdomen convinced me that this was not a case of peritonitis, for the painful part was too circumscribed, and there was some tolerance of pressure with the finger over the right iliac region, while the other side was exceedingly sensitive and painful.

In order to relieve the pain, if possible, and to ascertain whether its origin was ovarian, I ordered the following, which has proved of value in such cases:

R Ammonia mur., ʒj;
Tinct. aconiti, fʒj;
Syr. aurant., fʒiv.

M. et sig. Dose, one teaspoonful three times a day.

No favorable results followed its administration.

Thus, it will be seen, I arrived at a point—from a series of negative confirmations, viz., it was not a miscarriage, not carcinoma, not peritonitis, not ovaritis—where I could fix my diagnosis.

At this stage of the case (about the 26th of July) I announced to the patient and her husband my diagnosis of the case,—extra-uterine pregnancy. From August 4 to August 8 her symptoms were greatly aggravated. The persistent efforts to vomit (although her stomach was entirely empty) seemed to rack her entire system, and I began to fear that she would sink from the exhaustion induced by them. Remedies were of no avail. On the 7th of August she seemed very bilious, having had no evacuation for two days. Five grains of mass. hydr. administered, and the dose repeated in five hours. Citrate of magnesia was ordered on the morning of the 8th. Soon after some blood-clots passed from the rectum, and one arm of a foetus. Saturday morning, August 9, while having an evacuation, she felt something engaged in the anus that she was unable to pass. It was removed by her nurse, and proved to be the larger portion of a foetus, with the placenta and cord attached. One hand with the arm was perfect. It was a foetus of about ten weeks,

and, although somewhat decomposed, is carefully preserved, as an interesting specimen, in the U.S.A. Medical Museum.

The following is a history of the case from the date of the expulsion of the fœtus, August 9, 1873.

I was sent for as soon as the fœtus passed, but did not see my patient (as I was detained by other engagements) until 1 P.M. She had been suffering from faintness and nausea, and had passed several blood-clots per anum. In reply to my question, "How do you feel now?" she said, "I feel a constant desire to pass fecal matter, and this is accompanied with pain in the left side, and nausea." I at once made an examination per vaginam. The os and cervix were in a normal condition. There was no indication of dilatation. The os was no more patulous than on my previous examination. When I removed my finger there was no trace of blood upon it. I then passed the forefinger into the rectum. The operation was attended with great pain to the patient. The temperature of the part was greatly increased, and on withdrawing the finger it was found covered with blood, and what seemed to partake of the character of pus. I at once placed a folded napkin against the vulva, and directed that it be examined after more clots passed. This proved that the clots came from the anus, as the napkin was unsoiled. Pulse weak, and 100. Some fever, with thirst, and occasional chilliness. Ordered beef-essence and brandy, alternate hours; turpentine stupes to the abdomen, and enemata of solution of starch, turpentine, and laudanum three times a day; hot bricks to the feet; no solid food; hypodermic injection at night; gave ice freely; vin. ferri et cibi, fʒss three times a day.

August 10.—Patient restless and feverish. Slept some last night. Pulse 118; surface moist (cold perspiration); skin sallow; great thirst, and pain in the left side, passing thence to other parts, as the back and breast. Treatment continued.

August 11.—Has passed some blood per anum since yesterday. Pulse 120; extremities inclined to be cold; complexion sallow; expression bad; complains of thirst, debility, and a constant desire to defecate. Abdomen is smaller, and less tender. Slept without hypodermic injection, awaking about every two hours. Treatment continued, substituting beef-essence for solution of starch in the enemata.

August 12.—Had a bad night until one-third of a grain of morphia was injected hypodermically. Pulse 118; complexion and expression bad. Pain seems to have moved higher up the left side. She suffered much from nausea until the morphine was administered, after which her stomach became quiet. The morphine quieted her, but she did not sleep. Temperature, morning, 99½°; noon, 100°; night, 101°. Treatment unchanged.

August 13.—Bowels moved slightly last night. Pulse 110; temperature, 6 A.M., 99°; 12 M., 99½°; 6 P.M., 99°. Complains of pain higher up. Stomach very irritable. Had a restless night,—somewhat delirious. Gave less brandy; otherwise, treatment continued.

August 14.—Tongue red and dry; great thirst; pulse 102; pain has moderated, but there is great tenderness over the pit of the stomach. Circulation bad, as evidenced by coldness of hands and feet; at times flighty, desiring to get out of bed; temperature, 7½ A.M., 97°; 12 M., 98½°; 6 P.M., 101°; did not rest well last night.

R Ol. terebinth., fʒjss;
Pulv. acac.,
Pulv. sacch. alb., āā ʒij;
Tinct. opii,
Spt. lavand. co., āā fʒj;
Aq. puræ usque ad ʒij.

Ft. emulsio.

Sig.—One teaspoonful every three hours.

August 15.—Bowels moved last night. Pulse 108; tongue moist, and symptoms better; no pain, but great debility; expression is decidedly better, and she seems more cheerful; temperature, 6 A.M., 98½°; 12 M., 99°; 6 P.M., 100½°.

August 16.—Had a good night. Pulse 102; bowels moved three times during the night; the last time she passed some debris of the fœtus that had been retained when the mass came away; complains of pain in the pit of the stomach, and cannot retain the emulsion; tongue not so moist as yesterday; circulation not so good; it is with difficulty that her hands and feet are kept warm; temperature, 6 A.M., 98°; 12 M., 98°; 6 P.M., 98½°. Suspend the emulsion, continue the other treatment.

August 17.—Rested well last night, and seems to be better. Pulse 102; no fever; very little pain and thirst; desires more substantial diet, as she "feels hungry;" bowels moved last night; circulation evidently improved; temperature, 6 A.M., 99°; 12 M., 99°; 6 P.M., 100½°. Treatment continued.

August 18.—Doing well. No pain, save when she coughs; had a slight night-sweat last night; pulse 96; temperature, 6 A.M., 98½°; 12 M., 99½°; 6 P.M., 100°; took some cracker in her chicken-broth last night, and feels that she is becoming stronger. No change in treatment.

August 19.—She is very comfortable to-day; seems quite free from fever; no pain in the side, but tenderness on pressure over the uterus; was raised up in bed for a few minutes, while her pillows were adjusted. Pulse 102; temperature, 6 A.M., 98½°; 12 M., 99°; 6 P.M., 100½°. Takes the vin. ferri et cibi three times a day, broth, soup, or beef-tea, with brandy.

August 20.—Complained to-day of some pain in the left side; relieved by a turpentine stupe; not so much tenderness over the uterus; had a small evacuation, perfectly natural, no pain; has some fever at night, and requires the morphine; pulse 102; temperature, 6 A.M., 98°; 12 M., 99°; 6 P.M., 101°. Took a soft-boiled egg this morning, as her appetite is improving.

August 21.—Up to this date have made my visit in the morning, only calling at night when I deemed it necessary. Deferred my visit to-day until 8 P.M. Has been very comfortable all day, but had a restless night until the morphine was given. Pulse 108; tongue moist; extremities cool and moist; appetite improving; temperature, 6 A.M., 98°; 12 M., 98°; 6 P.M., 99½°.

August 22.—Saw her at 7½ P.M.; has some fever; pulse 108; some pain in left side; temperature, 6 A.M., 98°; 12 M., 97½°; 6 P.M., 99½°.

August 23.—No pain in the abdomen; had a severe headache last night, and did not sleep, although the hypodermic injection was given; took a little raw beef to-day; pulse 96; temperature, 6 A.M., 98°; 12 M., 98°; 6 P.M., 99½°; tongue moist, and symptoms generally favorable.

August 24.—Had severe pain in the abdomen last night, and two evacuations, caused probably by eating a few grapes; has some fever to-day; has vomited what seemed both sour and bitter to her; has been suffering from ardor urinæ; decoction of uva ursi, with flaxseed tea, ordered; pulse 96; temperature, 6 A.M., 96½°; 12 M., 98°; 6 P.M., 100°.

August 25.—Was restless last night until the injection of morphine was given; has felt (as she expresses it) a drawing sensation in the left iliac region, similar to that attending the application of cups; pulse 90; temperature, 6 A.M., 98°; 12 M., 98°; 6 P.M., 100°.

August 26.—Complains of a tightness or drawing in the left side of the abdomen (lumbar region), but no pain; suffered some from nausea last night; had an evacuation, and it contained much mucus; ardor urinæ relieved; pulse 90; temperature, 6 A.M., 98½°; 12 M., 98°; 6 P.M., 100°.

August 27.—Does not rest at night unless she has the morphine; has pain in her back, probably from remaining too long in one position; gentle pressure upon the abdomen causes no pain; every attempt to straighten the left leg causes a sensation of drawing or tightness in the left side of the abdomen; pulse 96; temperature, 6 A.M., 98°; 12 M., 98°; 6 P.M., 99°.

August 28.—Had some fever last night, and vomited bile; complained of sharp pain in left lumbar region, extending into the groin and to the right side of the back; appetite is failing; extremities rather cool and moist; stimulants ordered to be taken in larger doses; she has taken but little of them during the last week; mass. hydr., gr. iij, to be given this P.M.; pulse 88; temperature, 6 A.M., 97°; 12 M., 96½°; 6 P.M., 99½°.

August 29.—Was very restless last night until gr. ¼ morphia was injected; to-day pulse is 80, skin cool and moist; has felt some pain in the womb, and passed wind per vaginam; temperature, 6 A.M., 97°; 12 M., 98°; 6 P.M., 100½°; had an evacuation, passed bile, and feels very comfortable.

August 30.—Had slight fever last night, and some nausea, which the injection of morphia relieved; has some pain in the left lumbar space to-day, but can extend the left limb with less difficulty, and with but little or none of that drawing in the left side; pulse 96; temperature, 6 A.M., 98°; 12 M., 98°; 6 P.M., 98½°.

August 31.—Felt some "cutting pains" in left side last night; had a yellowish discharge from the vagina, accompanied with a throbbing pain in the womb; pulse 80; temperature, 6 A.M., 98°; 12 M., 98½°; 6 P.M., 99½°.

September 1.—Sat up in a chair ten minutes to-day; has no pain when quiet, but is very weak; pulse 78; temperature, 6 A.M., 97½°; 12 M., 98°; 6 P.M., 98½°.

September 2.—Did not feel so well to-day, and had quite a fever at night; pulse 80; temperature, 6 A.M., 97½°; 12 M., 98°; 6 P.M., 98½°.

September 3.—Feels much better to-day, and is doing well.

At this stage of the case, on account of a misunderstanding with the husband relative to the *quid pro quo*, my ministrations ceased, the patient passing to the care of Dr. Lincoln, of this city.

The notes of this case were taken with care at the bedside of the patient, and no pains spared to make the history both correct and complete. After the expulsion of the foetus every symptom or change of any moment was duly noted, for the purpose of procuring an exact history of the phenomena incident to extra-uterine foetation. Full reports of such cases are rare. In Dr. Garland's case, a brief report of which was copied in a late issue of *The Philadelphia Medical Times* from the *Boston Medical and Surgical Journal*, "the last piece of bone was discharged on May 4." He then remarks as follows:

"Under the most sustaining treatment, the patient gradually sank, and died on the 20th of May, 1872."

An exact history of the case during these sixteen days—the stage of the pulse, temperature, nature and frequency of the evacuations, and general condition of the patient—would be of real interest.

Fortunately, in my case no opportunity was afforded for an autopsy; but a careful study of the case has led me to the following conclusions:

It is my impression that conception occurred just after the menstrual period, March 13, 1873; that the symptoms attending the return of her period four weeks later were in a great measure due to the fact that the pregnancy was abnormal, and as

the foetus increased in size it caused pain by pressure upon the parts with which it was in contact. I strongly suspect that the grave symptoms upon the return of her third period in June were induced by the passage of the foetus with the placenta into the colon, as adhesion, softening, and consequent breaking down of the tissues of the large intestine must have taken place, otherwise the foetus would have remained in the abdominal cavity.

Now, admitting conception to have taken place about the middle of March, 1873, and arrest of development to have occurred early in June, we should find, as in this case, a foetus of about ten weeks.

As regards the temperature in this case, at no time, it will be seen, did this exceed 101°, while on the 24th and 28th of August it fell to 96¾° and 96½°. Dr. Aitken ("Science and Practice of Medicine," vol. i. p. 48) says, "When it is found in a bad case of typhoid fever that some morning about the third week the temperature has fallen to 99.5°, the reparative stage has begun, the healing of Peyer's patches."

We ask, therefore, did not the low temperature on the 24th of August mark a favorable crisis in this case, so far as the condition of the intestine was concerned? We had expected (after the passage of the foetus) to find the temperature ranging with that of typhoid (enteric) fever. In this we were mistaken. Why did the temperature never exceed 101°, and why should it fall so low as 96½°? Excessive loss of blood will cause a decline in temperature. That condition did not obtain in the present case, for the small amount of blood lost after the expulsion of the foetus led me to believe that my patient might recover. Had there been profuse hemorrhage I should have anticipated an unfavorable result.

Another interesting question presents itself as regards this case. Where did impregnation take place? In the ovary, I believe, and before the ovule left the Graafian vesicle. Why? Because when it occurs in the Fallopian tube and the ovule fails to pass into the womb, rupture of the tube is generally attended with fatal hemorrhage (Ramsbotham, p. 575). I consider this a case of sub-peritoneo-pelvic pregnancy, the second in Cazeaux's classification, "in which the ovule, after having quitted the ovarian vesicle, is unable to pass into the Fallopian tube, but gets between the two laminae of the broad ligament, and is there developed. Of course the ovule is situated without the peritoneum, and it lodges principally in the pelvic cavity." The same author adds (p. 261), "In this variety the product of conception, by occupying the pelvic excavation, displaces and compresses the organs there situated,—the vagina and rectum, for instance,—and pushes them to one side." This condition would have obtained in our case, but for the early arrest of development, as evidenced by the extreme sensitiveness of the vagina, and the marked prominence in the lower portion of the left lumbar region just above and to the inside of the sigmoid flexure.

Taking it for granted that this prominence or swelling marked the position of the foetus and pla-

centa, we infer that they must have entered the descending colon at a point just above the sigmoid flexure. The capacity of the bowel in this quarter strongly favors such a supposition.

Ramsbotham (p. 583) informs us that he had known of fourteen cases of extra-uterine foetation, with the following results. Ten died, four recovered. Two passed the bones per anum; from one the foetus was extracted by incision; the other recovered, the foetus remaining within her.

October 31, 1873.—In a conversation with Dr. Lincoln to-day, he informed me that he made but a few visits before he found Mrs. J. down-stairs and able to walk about. Since that he had not seen her. "You had got her through all right, doctor, and there was nothing for me to do," he remarked.

I believe that the morphine administered hypodermically, while it often failed to produce sleep, quieted the nervous irritability,—a great point to be gained,—and proved very valuable in this case. While in some instances I have seen excessive vomiting follow its administration by this method, a contrary effect obtained here. The nausea was greatly relieved by it. To the careful use of morphine hypodermically, to the prompt meeting of indications as they appeared, to a faithful adherence to the sustaining treatment, and to the determination of my patient not to die, I attribute her recovery from a condition that generally proves speedy and surely fatal.

WASHINGTON, D.C., November 3, 1873.

SOME OF THE CAUSES OF HÆMOPTYSIS.

BY HORACE Y. EVANS, M.D.

THERE is scarcely an event occurring in the general practice of medicine, except it be post-partum flooding, that so shocks and, to an extent, paralyzes the physician, as copious hæmoptysis.

Notwithstanding the conviction of the experienced that this hemorrhage rarely proceeds so far as to produce immediate death, yet, remembering that the blood is life, and to see that life, as it were, gushing from both mouth and nostrils, and that, too, from a being already chlorotic from a wasting disease in a vital organ, is sufficient to disturb the equanimity of the most deliberate.

This loss of blood may arise from various causes, and at various periods of health and disease.

The causes may be conveniently, and to a certain extent truly, divided into two classes,—those external to the body, and those internal, or arising as a result of a diseased condition. Of the first, we have mechanical injuries to the chest, such as penetrating wounds. During the late war of the rebellion this was not an uncommon event in the experience of many of us. So also from fracture of the ribs, spiculæ of bone penetrating the lung-tissue, the inhalation of caustic fumes and particles of irritating dust, as in the case of file-makers or those employed in grinding and polishing metals. It frequently results from excessive physical exertion, as in straining, or lifting heavy bodies. The forced retention of air in the lungs whilst the ab-

dominal and thoracic muscles are rigidly contracting will, in many cases, produce either an emphysematous condition or a complete laceration of the viscus with its contained plexuses of arteries and veins.

Of the second class, catarrh may be named as occasionally causing hemorrhage; though the uncomplicated attacks usually traceable to this cause are of so slight a character that we are forced to the conclusion that the bleeding is from the vessels on the larger bronchial surfaces, and not from the lungs proper.

Another very fruitful cause of this hemorrhage, and one frequently not recognized, is disease of the left side of the heart. The defective mitral valve, with its indurated, contracted, and weakened segments, no longer protects the delicate lung-structures against the powerful contractions of the left ventricle, and, as a consequence, regurgitation takes place, thus keeping up a constant and forced dilatation of the pulmonary vessels. These sooner or later give way, producing the most annoying and obstinate attacks of hæmoptysis with which we meet. Indeed, there is no more unfortunate complication with which the consumptive can be afflicted than this same disease of the heart.

We have also what are called vicarious hemorrhages,—those following the interruption of habitual discharges, such as hemorrhoidal or menstrual. They are occasionally serious, yet by that remarkable law of accommodation in nature the vessels soon become reconciled to the excess of blood, and it flows on submissively in the natural channels. Notwithstanding the facility with which we can thus rationally account for almost every form of hæmoptysis, we usually associate its occurrence with an internal and far more grave disorder than any of which we have as yet spoken,—viz., the incipency or full-fledged existence of consumption.

Authorities differ widely in regard to the relationship existing between this hemorrhage and the presence of tubercles in the lungs. Launce, Louis, Rokitansky, Watson, Williams, and many of our own writers, associate the two as almost invariably dependent the one upon the other. Either the hemorrhage, by its subsequent clots, creates a local irritation, congestion, and inflammation, thus clogging the channels of nutrition, the lymphatic glands degenerate and are converted into tubercles, or the whole mass becomes cretaceous phthisis; or, on the other hand, fully-developed and softening tubercles by the ulcerative process open a pulmonary vessel and thus act as a direct cause of hemorrhage. Though there may be valid reasons for rejecting hæmoptysis as pathognomonic of consumption in the early stage, yet in the latter it becomes a direct result, pointing to softening and actual destruction of lung-substance. There are, undoubtedly, numerous instances in which hemorrhage has been frequent and copious without terminating in disease; yet it is a well-established pathological fact that in cases of tubercular cachexia there exists a fragile state of the blood-vessels not usually found in other diseases. This degenerating tendency, so characteristic of consumption, greatly

favors, and is the only way of accounting for, this bleeding in the early stage, when the physical signs do not as yet indicate disease. We have often watched, and with a degree of certainty predicted, hemorrhage in the early stages of phthisis. The history and symptoms of such a case would be about as follows. An irritating, short, and dry cough, traceable to a slight cold contracted a few days previously; great oppression, difficulty in breathing, loss of appetite, thirst, continued fever; pulse rarely under 100; temperature from 100° to 104°; expectoration very slight, and of a saltish taste. Percussion-signs at first almost nil. Auscultation would reveal dry tubular sounds over a part of one or both lungs. Respiration rapid, with *prolonged* expiration. These symptoms would gradually become aggravated, continuing for several days, when, after an unusually severe attack of coughing, hemorrhage would commence. The relief following this occurrence sustains our explanation,—viz., the existence in the first place of tubercular deposits to an extent not as yet recognizable by physical signs nor incompatible with the normal functions of the lungs. But the catarrh awakens the fire; the flames spread rapidly to the miliary centres already existing, and, upon the principle of *ubi irritatio ibi affluxus*, an active congestion results, and the degenerated and enfeebled blood-vessels, unable to endure the pressure, give way.

The main cause, however, in the advanced stage, and the one resulting in the most copious loss of blood, is the dilatation and thinning of the pulmonary blood-vessels. By some authors it has been named ectasis, or aneurism; but to the sight and touch in the cadaver it resembles the varicose condition often found in the veins of the lower extremities. In the process of softening and conversion of the tubercular or adenoid substance into pus, cavities are formed, through or on the walls of which the pulmonary vessels pass; by the loss of structure they are exposed, the normal support of the lung-tissue is removed, and the vessels dilate and eventually burst.

This event may occur in the formation or emptying of each successive abscess. The progress of the disease to a fatal termination depends upon the rapidity with which one abscess follows another.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS, M.D.

Reported by JOHN B. ROBERTS.

TUBERCULOSIS OF THE SPINE.

THIS little child has angular curvature of the spine from caries of the bodies of the vertebræ, as is shown by this projection in the middle of the dorsal region. This affection, frequently called Pott's disease, is dependent upon deposits of tubercular matter in the arcular structure of the vertebral bodies, and is in its nature essentially like the tuberculosis of the hip and

other joints that is found so frequently in children of the strumous diathesis.

After deposition has occurred, softening and disintegration take place, utterly destroying the bodies of the vertebræ, so that the weight of the head and shoulders causes the spinal column to bend forward, and the spinous processes, which are not affected by the disease, to project unnaturally and make a protuberance upon the back. The amount of deformity produced is governed by the number of vertebræ involved, and when several of these are destroyed the contour of the chest is very materially changed, the ribs and sternum being forced to assume a horizontal position.

The pus formed may be discharged in the neighborhood of the disease, or, by travelling downward, form a lumbar or psoas abscess.

The affection occurs in children of a strumous diathesis, and usually before the age of ten; though cases are occasionally seen where the patient has attained adult years.

The child first becomes weak and delicate, has cold extremities and a tumid belly, and is awakened during the night by spasmodic pains in the chest and abdomen resembling neuralgia. Pain upon pressure is then noticed, and difficulty in progression occurs, as shown by the peculiar gait assumed by the little patient, who walks with the body inclined forward, the head bent backward, and the feet widely separated and scarcely raised from the floor, to avoid concussions of the spine.

As the disease advances, paralysis of the extremities may supervene from compression of the spinal cord, caused by the angularity of the column at the seat of morbid action; and, as the pressure is first brought to bear upon the anterior portion of the cord, the function of motion is generally impaired before sensation.

The treatment of caries of the spine consists essentially in absolute rest in the recumbent posture, so that the vertebral column may be relieved from sustaining the head and shoulders, which tend to increase the deformity as long as the diseased bones are compelled to support them. As soon, therefore, as the affection is recognized, the child should be confined in bed, upon a firm level mattress, without any, or at most with a very low, pillow, and should be kept there until repair takes place. This is accomplished by the formation of osseous material around the seat of disease, bridging, as it were, the gap left by the destruction of the bodies of the vertebræ, and affording support to the head and shoulders. In this position the patient must remain, not a few weeks or months, but until the cure is completed by the occurrence of firm ankylosis.

As the disease is a manifestation of constitutional vice, such internal remedies as will build up the system must be employed: hence cod-liver oil, quinine, and the ferruginous preparations should be administered, and the child given the benefit of the best possible hygienic surroundings.

GOITRE.

Mary S., aged 14, and born in this country, comes to the clinic with a swelling in the neck, for which she requests treatment. This is simply a case of goitre, or chronic hypertrophy of the thyroid gland, which is rather an unusual affection among natives of this country, though often met with in certain sections of Europe, where, indeed, in some places, as in the valleys of Switzerland, it is endemic, and frequently associated with that peculiar form of idiocy known as cretinism.

Goitre, or bronchocele, which, by the way, is not confined to the human subject, but has been observed also in the inferior animals, occurs chiefly in young persons, females more frequently than males, and may occasionally be hereditary. The skin over the swelling is free from discoloration, and there is usually no pain

connected with the progress of the disease unless a nerve be compressed by the morbid growth. The tumor generally increases slowly, but may in time attain great bulk, causing headache and epistaxis by obstructing the return of venous blood, and difficulty in respiration by the pressure exerted on the trachea and upon the phrenic and pneumogastric nerves.

There are numerous growths occurring in this situation which might make a diagnosis difficult, were it not that each has characteristics that in most instances render its nature apparent. Swelling of the lymphatic glands may be excluded when there are none enlarged in other portions of the neck, and when there is no history of strumous disease.

Aneurism, particularly of the carotid artery, might be confounded with goitre, but it is not liable to occur at such an early age, shows pulsation, has its peculiar whirr, and, moreover, is immovable. Cases, however, in which the bronchocele is large and developed laterally may readily be mistaken for aneurism, since the tumor, overlying the carotid artery, will transmit its pulsation; but the slowness of the growth, the absence of the aneurismal whirr, and the ease with which the tumor can be moved away from the cervical vessels will serve to distinguish the affections.

The most characteristic feature of goitre is its ascent and descent with the trachea during the act of deglutition. Hence, by also presenting this peculiarity, cystic tumors situated over the thyroid gland resemble goitre perhaps more than any other affection; but these are generally of small size, and can be recognized, if other means fail, by the use of the exploring-needle.

When the disease is in its early stages and no organic change of structure has taken place, much can be effected by treatment, and even the entire disappearance of the tumor may sometimes be attained.

The administration, internally, of the preparations of iodine, the corrosive chloride of mercury, or the muriate of ammonia is found to be attended with very beneficial results; while sorbefacient lotions and unguents, such as tincture of iodine and ointment of the red iodide of mercury, are employed externally to excite the action of the absorbents. The detraction of blood by leeches placed over the swelling will also be productive of a great deal of good in many cases.

This girl shall rub thoroughly into the skin over the goitre a small amount of the ointment of the red iodide of mercury diluted with seven parts of simple cerate, and internally she shall take seven drops of Lugol's solution of iodine.

BELLEVUE HOSPITAL, NEW YORK.

Reported by W. H. FARRINGTON, M.D.

MALIGNANT DISEASE OF THE TESTICLE.

D. M., æt. 17 months, American, admitted November 1, 1873. Family history good. At birth the right testicle was noticed to be enlarged to about the size of an English walnut, and hard. For the first week after birth the testicle was drawn up tightly against the external ring; then it descended into the scrotum lower than the other. During the first year of life the testicle remained in about the same condition, not enlarging predominantly over the left, the integument preserving its normal appearance. The child was carried to a medical college for examination, and an exploring-needle introduced. What the exploration revealed is unknown; but one week later three incisions were made into the tumor, quite profuse hemorrhage following the operation. For a day or two the tumor decreased in size, then began to enlarge, no pain appearing to accompany its growth. The integument

assumed a brownish discoloration. The child's health did not suffer in the least.

On admission, the general appearance is that of health; appetite good; bowels regular; child is bright and cheerful. The right testicle is enlarged to the size of a goose-egg; the spermatic cord is elongated, and the scrotum distended, reaching to within an inch of the knee. Considerable dusky discoloration exists in the scrotum, especially on the right side; but no ulceration is detected.

November 1, 1.30 P.M.—Patient anæsthetized and an exploratory incision made by Prof. J. R. Wood, revealing malignant disease of the medullary type. Enucleation of the organ was then performed, with trifling loss of blood. Patient rallied well from the operation, and was apparently comfortable until November 2, 2 A.M., when he became restless and seemed to be suffering from pain. At 6 A.M. he suddenly developed clonic convulsions. The dressings were removed, the child was placed in a hot-water bath, and a few drops of spirits of camphor were given, with little or no effect in arresting the convulsive movements. Chloroform was administered, and the convulsions ceased immediately, but returned in an hour, when they were again arrested by chloroform. Ordered sodium bromide, gr. ij every hour.

9 A.M.—Patient has muscular twitchings, confined mainly to the right side. Surface hot and dry; pulse rapid and weak. Ordered brandy, ℥v every half-hour.

12 M.—The muscular spasms are now limited to the flexors of the right forearm. Pupils slightly dilated; some oscillation of the eyeballs. Pulse has more force and less frequency; surface cooler. Brandy discontinued. Sodium bromide, gr. ij every two hours, ordered. Patient refuses to nurse.

4 P.M.—Surface hot; pulse frequent and feeble; respiration rapid, and jerking muscular movements confined to right forearm. Brandy renewed as before.

November 3, 9 A.M.—Child slept none through the night. Has convulsive movements of right arm and face. Respirations rapid and laborious. Pulse rapid and feeble; skin hot and dry. Sponging of surface with tepid water ordered, and brandy, ℥v every half-hour.

12.30 P.M.—Patient moribund. Has muscular spasm in both arms and face.

2 P.M.—Died.

Autopsy not allowed by parents.

SUBACUTE PLEURISY—ASPIRATION—DEATH FROM SYNCOPÉ.

S. D., æt. 21, single, England, admitted June 7, 1873. Was admitted on the above date suffering from subacute pleurisy on the right side. On August 1 she was appointed night nurse, though still suffering from cough, dyspnoea, and pain in the right side, with physical evidences of fluid persisting in moderate quantity.

October 2.—Patient is compelled to relinquish her night service, and is readmitted as a patient. Pulse 132; respiration 48. Physical examination reveals dulness over the left lung, with absence of vocal fremitus over both sides. Respiration short and sharp on both sides, with a bronchial character, especially on the left side at the base, where it is distinctly bronchial. On right side respiration quite good to the base of the lung. Heart is pushed about two inches to the right of the sternum; the apex about the same distance to the left.

October 3.—Exploration with hypodermic syringe made, and clear serum obtained. Pulse 136; respiration 56; temperature 103½°. Patient has great dyspnoea, rendering speech almost impossible. Pulse feeble. Aspiration employed, only 3ij of serum being obtained.

6 P.M.—Patient still suffering as before. Ordered stimulants, and tincture digitalis 3j.

9.30.—Pulse stronger, and patient feels better. Aspi-

ration again employed, and four pints of fluid withdrawn slowly, without any feeling of discomfort to the patient. Respiration better; pulse gaining in strength.

11 P.M.—Patient resting quietly in bed.

11.15 P.M.—During the temporary absence of attendants, patient rose from her bed to the floor, and immediately fainted. Surface cold; face blanched; pulse feeble. Cold affusions to head employed, and hypodermic injection of whisky given, the pulse gaining temporary strength, but sinking again almost immediately. In a few seconds the patient died.

Autopsy.—Both lungs adherent to the pleuræ, which are thickened and contain a few miliary tubercles. In each cavity a few ounces of serum found, containing gelatinous lymph. Lower lobe of left lung compressed; lower lobe of right lung congested and œdematous. Point of aspiratory puncture appears only as a small spot of ecchymosis. Other organs healthy, with exception of bladder, which presents signs of inflammation.

ST. MARY'S HOSPITAL—DISPENSARY FOR NERVOUS DISEASES.

SERVICE OF CHARLES K. MILLS, M.D.

Reported by JOHN S. BAGG, M.D., Resident Physician.

HEMIPLEGIA.

A. M., æt. 36, married, had severe attacks of rheumatism at the ages of sixteen, twenty, and twenty-six; suffered also from slight rheumatic pains at irregular intervals up to the time of coming to the hospital. Six months before presenting herself for treatment, when several months pregnant, she was seized with vertigo while sweeping, at the same time experiencing intense pain in the back of the head. She lay down, but after a short time was able to go to her supper, and, while eating, her jaws became stiff, and she fell back paralyzed.

She was carried to bed, and remained there helpless, —three weeks later giving premature birth to a child, which lived but two days. She was confined to her bed six weeks in all, after which she could manage to hobble about. In the interval before applying to the hospital, four months and a half later, she stated that her condition varied, being better and worse by turns, but there was no decided improvement. During this time she was under no regular treatment.

On coming to the clinic she had marked hemiplegic facial paralysis of the left side. Her tongue was "thick," and protruded with difficulty. There was no ptosis, but slight convergent strabismus. She could not masticate on the affected side, and she had some trouble in swallowing. Her left arm hung lifelessly. She could not elevate it at all, except by inclining her body towards the right. The forearm was slightly flexed, but could not be moved by the patient. The fingers were tightly clenched, and could not be opened except by prying. The deltoid was slightly atrophied, as were also the muscles of the posterior scapular region. The left leg was dragged in walking, the left foot describing an arc as it was with great effort lifted. The toes were flexed. On examination, a blowing heart-murmur was discovered.

Owing to the still existing rheumatic tendency, iodide of potassium, in ten-grain doses, was given three times daily. Kneading of the muscles, and stimulating liniments, were ordered. One-twentieth of a grain of strychnia was given daily, and the left side was faradized twice weekly. This treatment was continued about a month, the patient slightly improving, when hypodermic injections of sulphate of strychnia were resorted to, with most decided benefit. After twelve injections of one-thirty-second of a grain had been

given hypodermically, the patient had almost regained the entire use of her paralyzed side, being able to open her fingers, elevate her arm, walk with very slight limp, etc. The hypodermic injections and faradization will still be continued.

TRANSLATIONS.

NITRITE OF AMYL.

HAVING his attention particularly directed to the nitrite of amyl by its effect in a case of angina pectoris, to which it gave immediate relief, Dr. Amezdroz (*Archives de Physiologie* for September, 1873) was led to study the literature of this subject, and to endeavor to ascertain by experiment the physiological action and therapeutic value of the drug. The article is briefly as follows:

When the vapor of nitrite of amyl is inhaled by man, it produces redness of the face, marked pulsation of the carotid and temporal arteries, occasional palpitation of the heart, sometimes a sensation of vertigo with headache, and an acceleration of the pulse. The cough excited in some cases by its inhalation is evidently due to the irritating effect of the vapor on the bronchial mucous membrane. Although no dangerous toxic results in man have yet been reported, because the feeling of distress and sickness which supervenes almost immediately upon the commencement of the experiment prevents a continuance of the inhalation, such results undoubtedly may be produced, because we know that it causes death in the lower animals. In these the first effect is great restlessness; the animal sneezes, and struggles to get away; the respiration becomes quickened and fuller, and occasionally stops. These respiratory troubles cannot be considered as a specific symptom of the intoxication by nitrite of amyl; they are more probably due to direct irritation of the bronchial passages: besides, the injection of any liquid whatever into a vein generally produces a sense of oppression, and acceleration of the respiratory movements. The action of the heart becomes equally increased, and the thoracic wall is visibly moved by its strong pulsations. Following this are alternating tonic and clonic contractions in the extremities, and even in the face; then opisthotonos, shivering, involuntary exertions, vomiting, and coma. Post-mortem results are not very marked, except the dark color of the blood, and the dilated, engorged heart; death being produced, apparently, by paralysis of this organ.

The method adopted for the administration of the nitrite of amyl is of great importance. The means by which the toxic effect is produced most quickly is by injection into a vein; the symptoms show themselves immediately, and rapidly pass off. It is surprising to note the amount of urine passed by the animal immediately after such an injection, although the bladder may seem to have been completely emptied but a few moments before; this occurs with each injection. It would have been of interest had a chemical analysis of this urine been made; but this was, unfortunately, omitted. By inhalation death can be produced by a comparatively smaller amount; though the symptoms are not so marked, and the inhalation must be continued for some time in order to produce external manifestations. By hypodermic injection the substance reaches the blood so slowly that it produces but little effect, the elimination taking place so rapidly that there is not at any time a sufficient quantity in the organism to produce the characteristic symptoms. As for the digestive tube, it seems to possess no decided advantages, but to be on about the same footing as the subcutaneous in-

jection. The administration by inhalation being more energetic, and at the same time watched with facility, it is natural that physicians should have unanimously preferred this to its internal exhibition, which has been abandoned. Following the administration of the nitrite of amyl, there is a marked decrease in the intervacular pressure, as shown by the manometer in all the experiments. There is also a constant dilatation of the capillaries, or, more properly, the fine arterial ramifications, which was not seen in the fine venules, and was but partially found in the capillary net-work proper.

This dilatation is evident soon after the inhalation is commenced, increases sometimes to double the calibre of the vessel, and, after a certain time (fifteen to twenty minutes), diminishes again, whether the inhalation is continued or not. This contraction continues until the vessel is smaller than before the inhalation. If the experiment is repeated, the phenomena are reproduced, but more rapidly. There is also a constant slowing of the capillary circulation, which follows the dilatation, and may be due to the lessening of the pressure. During the muscular spasms of the animal, the dilated vessels become momentarily smaller, and the circulation more rapid; but when the animal becomes quiet the effect of the nitrite of amyl is re-established.

The lowering of the blood-pressure and the capillary dilatation could only be produced simultaneously by an intervention of the vaso-motor nervous system, central or peripheral, or by automatic change in the walls of the vessels. A weakening of the heart's action cannot be considered as the cause, for that alone would not produce capillary dilatation: this must therefore precede the lowering of the tension, which would be the natural consequence of such dilatation.

A toxic effect upon the vaso-motor centres in the medulla would naturally appear to be the explanation of these phenomena, because direct or reflex irritation of that ganglion produces a diminution of the tonicity of the walls of the vessels. The nitrite of amyl is able to act in two ways upon the vaso-motor nervous centre: either by being brought by the blood directly in contact with that important organ, or by reflex action from irritation of the peripheral nerves. The limited extent of this nervous centre, and the small amount of blood conveyed to it, exclude the first hypothesis, while it is easily seen that by irritation of the peripheral ramifications of the pneumogastric, or some other nerve, the nitrite of amyl may produce a reflex irritation of the vaso-motor centres, and hence a diminution of the tonicity of the vascular walls. Two alternatives remain: either that the peripheral extremities of the vaso-motor nerves are affected, or the intimate muscular fibre of the vessels; but, as this leads us to the vexed question of muscular irritability, which we prefer not to discuss, we will merely state the fact that under the influence of nitrite of amyl constant dilatation of the pupil does not occur, which demolishes the theory of Brunton, who argued that from this dilatation we might infer a similar action in all the unstriated muscular fibres. Let it be the one or the other, the blood is really the irritating medium; and, rather than admit a direct action of the nitrite of amyl, which is not probable, we are disposed to take into consideration its chemical effect.

We know that it acts energetically in preventing the oxidation of bodies, and particularly that of the blood, also interfering with the elimination of its carbonic acid. This is corroborated by the post-mortem appearance of the heart and the arteries, which are filled with very dark blood. In conformity with the theories now generally admitted, this blood charged with carbonic acid, by strongly irritating the peripheral vaso-motor nervous filaments or the muscular fibres themselves, might rapidly induce a condition of paralysis

leading to dilatation. In company with certain distinguished physiologists, we adopt the theory that there are two species of muscular fibres in the walls of the vessels. The nitrite of amyl produces an irritation of those fibres which preside over dilatation, while those that govern contraction are unaffected by it.

The acceleration of the heart's action depends upon the capillary dilatation. In those cases where it is very marked, as after a large injection into a vein, it is possible that the ganglia which give to the heart its automatic motion are also affected by it; and, if it be pushed too far, death may supervene from paralysis of the heart.

The therapeutic employment of the nitrite of amyl is based upon these facts, and is particularly indicated where there is probable spasmodic contraction of the capillaries. If it has not always answered to the expectations of those who have used it, it is because it has often been improperly employed. Resting on a physiological basis so clearly defined, the new remedy holds an elevated position at the side of digitalis; and we hope that new experiments will soon be made to determine under what circumstances the physician may employ it with success, so as to contribute towards obtaining for it the right of introduction into the *Materia Medica*.

FRANK WOODBURY, M.D.

THE TEMPERATURE OF THE BODY AS AN AID IN THE DIAGNOSIS OF SOME FORMS OF SYPHILITIC DISEASE.

By DR. BÄUMBEER (*Deutsches Archiv für Klin. Med.*).

THESE observations were made upon patients suffering from the three following forms of syphilis: 1. Pustular syphiloids of the eruptive stage. 2. Rheumatoid forms of syphilis. 3. Ulcerative syphilis. The first case observed was that of a man with intermittent fever of a quotidian type, who three months previously had had an indurated sore, and at the time of observation had a pustular eruption, which later became ulcerative. Every evening for ten days the patient took five grains of quinine; but, as no effect was produced, the inunction treatment with mercurial ointment was ordered. After the tenth inunction a remission of the febrile symptoms was noticed, but eight days later the fever and the syphilitic pains returned.

The rheumatic forms of syphilis were observed in numerous patients, and under various conditions: in some cases, as swelling of the joints and acute or chronic periosteal trouble; in others, again, as affections of the fibrous tissues around the joints and bones; and in a third class of cases simulating very closely acute articular rheumatism. Some of the cases with periosteal affections presented a great similarity to chronic phthisis in the well-marked remissions they manifested. Dr. Bäumbeer convinced himself of the syphilitic origin of the disease by the result of treatment with iodide of potassium. A woman aged 29, with infiltration of the apices of both lungs, and enlargement of the spleen, suffered from ulcerative syphilis, and presented a well-marked variation in her morning and evening temperature. The use of quinine had no effect in lowering the temperature of this patient, but the use of the iodide of potash effected this at once, although there was a fresh outbreak of the ulcerative process in the pharynx, and upon the calf of the leg and on other portions of the body. Dr. Bäumbeer thinks that this form of remittent fever takes its start from the masses of exudation, and that a pyrogenic matter is formed in them which is peculiarly susceptible to the action of iodide of potash, while in other forms of remittent fever this drug is without influence.

WM. ASHBRIDGE, M.D.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 22, 1873.

EDITORIAL.

PROFESSIONAL ADVERTISEMENT.

IN our last editorial with the above caption, for divers causes which it is not necessary to recapitulate, we objected to the newspaper cards of the Pennsylvania Hospital. We did not, however, give the most cogent reason for the abandonment of their publication,—namely, the fact that if one hospital is allowed to advertise in such manner, all hospitals must have the same privilege—for whilst the practice is sufficiently unbecoming and unjust in the case of a general hospital, it is much worse in that of a special hospital. The reason of our selecting the Pennsylvania Hospital as the point of attack was because personalities—*i.e.*, reflections on individuals—could in this way be best avoided, since the custom originated before any of the present staff were even students of medicine, and because in connection with *this* hospital originated that practice which, at first harmless, has grown into an evil, and has been mother of worse evils.

One of the great dangers of specialism is its tendency to run into quackery,—a tendency so marked that it would be very hard to draw the line between some noted specialists and the quack. The specialist of course assumes the position that he is superior in his own line to his colleague the general practitioner. Granting that he is so, it becomes him to take his place most modestly. As, however, his bread and butter are to be obtained not only through the general practitioner, but also through the recognition by the laity of his superiority and

their consequent spontaneous consultation of him, the temptation is immense for the specialist to constantly exalt or parade his knowledge on every fair opportunity, and, as he gradually grows less and less sensitive, to adopt more and more doubtful expedients for making himself known and appreciated among the general populace.

The larger the population of any centre, as already asserted, the greater the importance to the individual of advertisement. So in London the specialist thrusts himself forward far more boldly and persistently than with us. A recent English writer uses the following language, which, we are happy to be able to say, is not as yet in any case applicable to the Philadelphia specialist:

"It is not only the herbalist and the bone-setter, but, with shame be it said, it is nowadays the well-educated specialist who sings with quite as lusty a voice as they,—

" 'See here, see here, a doctor rare,
Who travels much at home;
Come take his pills,—they cure all ills,
Past, present, and to come.' "

Although, as just stated, we are in this matter far behind our transatlantic brethren, yet we have started upon the road, and, at the rate we are travelling, will soon overtake them, especially since the Council of the London College have put the brakes down pretty sharply.

The great objection we make, then, to the practice of our oldest hospital is that it has opened the gate very wide and made a smooth pathway for the specialist to travel. Day after day there appear in our public press advertisements of the Wills, Orthopædic, St. Mary's, and probably other hospitals, offering treatment of diseases of the nervous system, or diseases of this or that organ or set of organs, by Doctor this and that, residence so and so. Now, we want to know in what respect these cards differ in effect, if they do in spirit, from private cards. Why would it serve the purpose of Dr. Sly, dermatologist, any better to insert his private card in the newspaper than to have the managers of some hospital put it there for him and endorse him before the people with all the weight of their private and public influence?—saying, practically, Dr. Sly is a most eminent physician,—a specialist of such unrivalled ability and acknowledged eminence that we have secured his services for our institution.

If some unknown or young and uninfluential physician should modestly take perhaps the only way he has of making himself known, and simply put "oculist," or "aurist," or "dermatologist" upon his door-plate or window-shutter, he would be at least tabooed, if not actively proscribed, by the Philadelphia profession; and yet we see day after day the names

of men who are leaders among us appearing in the public press clothed only in the flimsy veil of a hospital card. We denounce the forbidding of the one and the allowing of the other, as a gross injustice,—an injustice which ought not to be tolerated by any right-minded body of men for an instant. We do not blame the physicians who are advertised; we censure no man for taking advantage of every chance to forward his own interests; and so long as the custom exists, and is allowed by the medical authorities, no blame is to be attached to any individual for allowing himself to float down with the current. To find fault with any one for not being a reformer is simply childish.

See, however, what the practice will lead us to in the near future, and what it has already led to in the present.

As is well known, both the Jefferson Medical College and the University of Pennsylvania have organized dispensary services with full corps of specialists. The University Hospital is *un fait accompli*, and that of the Jefferson no doubt will be soon: as a matter of course, if not to-day, some time in the next few years the specialists connected with these hospitals will be dignified with the titles of professors. Both the institutions named—be it said to their honor—have abstained from advertising their staffs. But if the present course be persisted in, sooner or later the incumbents of clinical chairs will use their positions for their own personal advantage. When the custom is sanctioned by the general consent of the profession, they would be false to themselves if they did not do it.

As is well known, the patients who come to the school hospitals are largely from out of town. If it be right to advertise in one secular paper, it is right to advertise in all. If motives of policy excuse our city institutions for advertising in the city, the same reasons would apply far more strongly to these institutions advertising in the country.

Suppose, then, a prominent card were placed in every newspaper in our own and the adjoining States by the institutions mentioned,—“Dr. —, Professor of Diseases of —; Residence, —:” with the prestige of the schools it would make the fortunes of all concerned. Your orthopædic and other special hospitals would appear, at least on paper, but as rush-lights. Think of it!—a displayed advertisement, magnificent wood-cut of buildings, long array of names, a concentration of force before the community; but that is what we are drifting to, unless some strong hands seize the helm and guide us elsewhere.

Perhaps the strongest objection that can be made

against public advertisements by hospitals of their staffs is to be found in the general looseness of sentiment on the subject engendered by a sense of the injustice of the procedure, and by the feeling, “If Dr. Sly can be advertised in that way with impunity and profit, I can do it in some other way.” Let us see what this has already led to.

We remember how, many years ago, in early boyhood, we gazed with awe-stricken eyes upon pictorial quackery,—the frightful ulcers, the distorted limbs, the alpine tumors, the ghastly faces, and the sweet, peaceful, nay, ecstatic countenances after the electric salve or the magic powder had worked its miracles. So vivid an impression was made upon us by these pictures that to this day we cannot forbear glancing over such sheets whenever they come in our way. For this reason, some weeks since, when an open pamphlet was put into our hands by a friend, we looked with interest at the pictures “before treatment” and “after treatment,” noticing especially the unusually good character of the cuts, and how the crooked had been made straight and the lame to leap like an hart. Judge of our astonishment, O reader! when, on turning to the title-page, we found that in our hands was the “Annual Report” of the Orthopædic Hospital, and that emblazoned on its front were the names and addresses of some of the foremost medical men in the city! Of course none of these gentlemen knew anything about this pamphlet until after it was published. Of course the photographs of their cases were taken, and the wood-cuts made, without their knowledge. With the greatest of pleasure we allow that the medical gentlemen were ignorant of, and consequently are in no sense responsible for, this action of the board of managers. We are confirmed in our judgment by noticing that at least some of the cuts are taken bodily from the catalogue of one of our instrument-makers!

“John Gilpin kissed his loving wife;
O'erjoyed was he to find
That, though on pleasure she was bent,
She had a frugal mind.”

The pamphlet is meant for circulation among the populace. It is arranged to appeal to the ignorant. Does any one suppose that a gentleman who has five or ten thousand dollars to give away will select any individual hospital because its report is studded with the “results of treatment”? No; but the artisan or the laborer whose child is afflicted may, if out of work, take the sufferer to the institution, or, what is more to the point, if the times be good, will consult Dr. — who has wrought the depicted miracles.

In what respect the spirit of this report is more commendable than that of certain institutions usually spoken of as "quack" we should be glad for some correspondent to point out to us. If it be suffered to go to a second edition without an earnest official protest from the medical board, the latter ought to be held in the strictest sense responsible for it. "*Shall not suffer*," says the Code.

Another indication of that growing demoralization whose seed is the practice of the Pennsylvania Hospital is the appearance in our daily papers of well-written and laudatory accounts of surgical operations performed by Doctor this or that.

It may possibly happen sometimes, but it must be very rarely, that the belauded operator really has no suspicion in regard to the publication before it is done. Of course he does not write the account; perhaps he may be able to say with a certain degree of truth that he did not know it was about to be published. In the great majority of cases, however, he could have known, if he had not suffered from a sort of moral or intellectual strabismus.

"Do you see him here now?" said the judge.

"No, I don't, my lord," replied Sam, staring right up into the lantern in the roof of the court.

"If you could have pointed him out, I would have committed him instantly," said the judge."

If a physician have knowledge or suspicion that an operation of his is to be mentioned in the public press, he is bound to prevent the article from being printed. The Code says, "shall not suffer such publications to be made." Of course he can prevent it, if he really try. No editor of a respectable paper would have the paragraph inserted, if he saw that the operator was really in earnest in trying to keep it out and made a personal matter of it. After all, it is a previous violation, in the great majority of cases, of the Code of Ethics, which gets a surgeon into difficulty. The Code forbids "to *invite laymen* to be present" at operations. Reporters do not haunt the medical lecture-room. It may be only a hint to a patient or a friend which starts the ball.

As some of our readers probably have heard, there is a medical society known as the Philadelphia College of Physicians,—a society supposed to comprise the *élite* of the profession,—to be aristocratic. Scientifically, this society is as dead as the equally aristocratic city of Annapolis,* or as the dry bones

in the valley of the prophet. It has been supposed that it is, however, the repository of professional ethics. Is this not so? Is the society to become only an expensively and awkwardly organized "library association"? Where are the censors of it? Why is the representative medical journal of the community forced to show forth our weaknesses to the world, as the only way of stopping the growing evil?

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held October 22, 1873, at 8 o'clock P.M.,

DR. W. B. ATKINSON, PRESIDENT, in the chair.

DR. O'HARA remarked that he had been in the habit of relieving frontal neuralgia by a wash of bay rum, vinegar, and water, of each half a pint, together with an ounce of the muriate of ammonia. Recently he had used it in a case of injury to the brain from concussion, for a period of three weeks, when it was found that quite a number of hairs had grown upon the scalp, which had been bald for several years. He had found since that it was quite a valuable hair tonic.

DR. TAYLOR said he had recently vaccinated a child of three and a half months, which after crying a few moments became quite hoarse, the voice having a croupy sound, which was soon reduced to a whisper, and finally was lost. This occurred whenever it cried, or even attempted to "crow," as it would do when pleased. He could perceive nothing unnatural about the fauces. The exterior of the larynx and thorax was perfectly normal, and the child quite fat. The parents had observed this peculiarity of voice since its birth, and thought it was croup; but as the child was perfectly well in every other respect, and a little rest brought its voice back again, they paid little attention to it. The doctor then asked some one to tell the cause.

DR. COHEN, in answer to Dr. TAYLOR, said that the loss of voice under excitement, such as had been just referred to, was caused by temporary paralysis of the muscles of the vocal cords, or because the spasm would not allow them to come together properly.

DR. H. Y. EVANS then read a paper entitled "Some of the Causes of Hæmoptysis" (which appears in the current number of this journal).

DR. COHEN remarked, on the subject of hæmoptysis, that the pathology set forth in the paper seemed to be correct. As regards treatment, he had some experience with ergot given internally and by inhalation. He thought it answered the same local purpose as the iron salts, and, in addition, promoted contraction of the small vessels. He generally used the tincture; but the fluid extract he thought did as well. When spray is used for the lungs, the inhaler should be held at least a foot from the person; when intended for the larynx, it should be held close to the mouth. One drop of iron salt to the ounce is sufficient to produce coagulation. The use of common salt is valuable. Its action, however, is not perfectly understood. His treatment is to keep the patient quiet, in a semi-erect position, and to give tannic or gallic acid, or acetate of lead, with opium. His patients generally carry a pill consisting of one grain of tannin and one-quarter of a grain of opium; sometimes he used the acetate of lead instead of the tannin. He

* Perhaps it may not be known to some of our readers that Annapolis is one of the oldest cities in the Union, and was settled by the *crème de la crème*. Not long since, mansions in good repair were sold for prices which did not equal the cost of the bricks in the garden-walls.

had not used ergotin by hypodermic injection, but thought favorably of it. In a case of scrofulous diathesis, in which epistaxis occurred, he used tannin by injection with an ordinary syringe, and the patient was greatly relieved.

Dr. EVANS remarked that in the copious bleeding of the late stages of phthisis the atomized Monsel's solution is the more prompt in its action, and should be the first employed. But the ergot, by its action upon the arterioles, is more permanent in its effects, and may be continued for several days without any objectionable results.

Dr. SLOCUM remarked that he had found ice useful in connection with other remedies.

Dr. ASH said that he had used the oil of erigeron in ten-drop doses with success. A medical friend, to whom he mentioned it, had also used it with marked benefit.

Dr. BUCK stated that his attention was first called to the use of erigeron by Dr. Samuel Jackson.

Dr. ATKINSON mentioned that the use of iron and ergotin in his own practice was attended with success.

Dr. TAYLOR had some success in arresting hemorrhage from the lungs by the use of five-grain doses of gallic acid every half-hour. Tone was then given to the weak and relaxed vessels, and the cough allayed by the use of sulphate of morphia, with five-drop doses of aromatic sulphuric acid every two or three hours, in the syrup of wild cherry.

Dr. STETLER had found the oil of turpentine most valuable. He thought its power in arresting hemorrhage was due to its general tonic properties.

Dr. McCREAN had used turpentine in hemorrhage from the piles. In the case of a druggist, he had always found it successful in doses varying from ten drops to a drachm.

Dr. BURNS said the subject was one of great importance and highly interesting. Unfortunately, his experience of this disease was more extensive than with many others, inasmuch as both his father and only brother had hemorrhages, extending over a period of twenty years. From this circumstance his medical attention was early called to the subject. When bleeding was in common use, he bled in most of these cases. In many cases of hæmoptysis the hemorrhage is due to a plethoric condition and weakened pulmonary vessels. He has bled while blood was yet flowing from the lung. He used this treatment in his brother's case: for fifteen years he bled him constantly, and always with decided benefit; but for the last five years of his life he was constrained to follow fashion, and did not bleed so much: however, in his case the same necessity did not exist, neither was his death produced by hemorrhage, but by disease of the liver. He only remembers one case in which bleeding was probably wrong, owing to the fact that the patient was in the last stage of phthisis and too weak.

He has bled oftentimes in epistaxis with marked benefit, but has now in a great measure discontinued venesection, relying more on medication, as we have more agents than in former years well adapted to combat such cases.

To arrest hemorrhages he uses sinapisms to the thorax, hot mustard pediluvia to the extremities, with the internal use of extract. secale and tinct. ferri chlorid., drachm doses of ol. terebinthinæ, followed by—R. plumbi acet., gr. ij; acid. tannic., gr. ij; opii, gr. ss; ft. pil. unam; capiat unam pro re nata. Ice and ice-water or iced lemonade for drink, with the chest well elevated.

To meet peculiarities, other means besides these have been used, as digitalis, sulphate of zinc, etc.

Dr. BURNS thought that the spray of various medical agents was worthy of consideration. He had used Monsel's salt of the strength of Ri to Zi , with marked advantage, in a severe case of hæmoptysis, and by injection with a small syringe, in epistaxis, with success.

He said that in the early period of his life, when threatened with pulmonary disease, he was an illustration of the advantage of blood-letting, having had that operation performed numerous times: on one occasion four pounds of blood were removed, under the supervision of the late Dr. Samuel Pickering, a disciple of the Rush school.

By this treatment, Dr. BURNS feels confident that he has been saved thus far from hæmoptysis and phthisis also, and he would not hesitate, under similar circumstances, to repeat it.

Dr. O'HARA remarked that among the remedies mentioned, he would like to call attention to the use of digitalis. In a case of hæmoptysis alternating with menorrhagia, he had always been able to correct the hemorrhage by a pill of digitalis and sulphate of iron.

Hæmoptysis depends upon many causes. If, as he supposes, in many of these cases hemorrhage is due to irregular or excited movements of the heart, then digitalis should act favorably in controlling epistaxis, hæmoptysis, and menorrhagia. Even where hemorrhage occurs independently of organic disease of the heart or any excited condition of the circulation, digitalis is highly beneficial. The late Dr. Brinton, as referred to in Ringer's Therapeutics, esteemed it in hæmoptysis. He states that it reduces the frequency of the pulse, when bleeding ceases. The infusion should be used, and large doses may be needed.

Dr. TAYLOR spoke of the benefit of venesection in hæmoptysis in the case of his uncle, who died at the age of seventy-four years. He had been subject to hemorrhages from the lungs from the age of thirty years, sometimes very severe. They occurred every few years, and he was treated during most of the time by the late Dr. Samuel Tucker, who invariably bled him and then gave small doses of the acetate of lead and opium. The old gentleman was constantly feeling and watching his pulse, and when it rose above the normal condition he would often send for a bleeder before he notified his physician. His cough was controlled by Dr. Samuel Jackson's pectoral mixture. So accustomed was he to these hemorrhages for many years that in his last illness he thought that if he had an attack of hæmoptysis he might recover again.

Dr. WELCH thought there was some danger of falling into the error of attributing too great remedial power to agents used for arresting hæmoptysis, and added that we should not forget that this affection rarely proves immediately fatal, and that the hemorrhage not unfrequently ceases of its own accord.

REVIEWS AND BOOK NOTICES.

AN ESSAY ON THE PRINCIPLES OF MENTAL HYGIENE. By D. A. GORTON, M.D. Philadelphia, J. B. Lipincott & Co., 1873.

The amount of wisdom wasted on the world is very great: in fact, the whole of mankind are like Bunyan's "Slough of Despond,"—ready to swallow up wholesome instruction by the cart-load, and grow rather the worse in so doing. This essay on mental hygiene might be metaphorically likened to a half-peck measure of wholesome instruction. Did we write wholesome? All apples are not ripe, and many of fair exterior cause cramps to the eater: yet are they not all sold by the measure? In some respects this essay is superior to most works of its class. It invades the treasury of general literature, and its flowers and simples are culled from a thousand fields. Its author is skilled in the use of the scissors. He says (page 11, preface), "He who reads the following pages . . . cannot fail to mark

the number of quotations introduced. Had I paraphrased freely, my paragraphs would have looked more original." We are glad he did not paraphrase; else should we have missed many rare sentences of Emerson, Coleridge, Bayard Taylor, Carpenter, Maudsley, Benjamin Rush, Winslow, Lecky, and so on, *ad infinitum*. And all these authors are brought before us to prove that in the matter of "the sublime unfolding of the human brain and mind, proper conditions are the antecedents indispensable to its highest realization in any department of nature or realm of matter or mind."

A certain similarity may be traced in all the works that issue from the press with the avowed aim of reforming the world. Dogmatic, eloquent with tinsel fire, wise with borrowed wisdom, strong in odd statistics, weak in logic and theology, they endeavor to show us how wrong we have all been and are,—except some few people who know better,—till the wonder grows, as we read, how we can go on so and continue to do so still,—how in the face of warning and anathema men will still eat improper food, which injures the mind,—live in hovels, which hinders æsthetic culture,—marry for physical beauty, or position, or money, or for any other reason than love and the highest adaptability and fitness, which causes their children to be vicious and immoral,—when they all know, or may know by reading this book, exactly what to eat, and wear, and live in, and whom they should marry; or, if they have doubts, the author of this book, or the many authors of many similar books, would tell them in a minute. How can men give way to temper, become ferocious, commit murders, when a diet of mush-and-milk would make them mild and gentle? Why will our legislators eat beef-steak, when bread and honey would render them incorruptible?—or our officials indulge in terrapin and oysters, when buttered toast would secure their honesty? And why, if these things are true, are we not all by this time, from President to election-repeater, upon an appropriate and rigidly-enforced system of diet?

The essay on the Principles of Mental Hygiene is wide in its scope. The little matters of diet commented on above are but as pebbles upon the margin of its ocean of facts and fancies. The author is an enemy of tobacco, and quotes Parton and Lizars. The work of the latter writer, however, on that topic, we had always regarded as quite unfit for serious quotation, it being more properly included among the curiosities of literature. Mr. Lizars considered that the use of tobacco produced cowardice; but the late European war certainly did not prove those perpetual smokers, the Germans, deficient in courage; and where smoker meets smoker upon the deadly field, would not such an effect of the weed be advantageous, by producing mutual fear and mutual suspension of hostilities? The author's own observations are rare: "While it must be freely admitted that many good and excellent men smoke, few such, I think, chew the weed;" and again, "The noblest types of manhood and womanhood generally have no affinity for the weed: indeed, I have seldom known a man, and never a woman, greatly distinguished for the high quality of his or her moral perceptions, who was an habitual or even an occasional user of tobacco." We could wish that the author had here indulged in statistics, giving us the number of men and women distinguished as above with whom he is intimately acquainted: a wider range of choice acquaintances might have given him broader views. On the other side he quotes Mr. Bayard Taylor as saying, "Many an impatient thought, many an angry word, have I avoided by a resort to the pipe," and cruelly adds, "But would not a glass of cold water have had a similar effect?" We fear, in the words of Touchstone, "that such a one is a natural philosopher," and, as such, beyond the reach of argument.

The author also has his word to say to the muscular student of the period: "The pugilist who is distinguished for muscle is never famous for brains. The celebrity in letters is notoriously deficient in muscular agility and development," but fails to quote as examples the late Professor Wilson and the Ettrick Shepherd. Also the author is a disciple of Gall and Spurzheim, and discovers by dissection such facts as "inordinate strength and activity of both the passions and intellect, while conscience and the moral brain in general were singularly defective." We were not aware that the presence of conscience could be demonstrated upon the cadaver; its absence and that of the moral brain in the majority of corpses we cheerfully admit.

Again, we find (page 106), "Hahnemann, . . . although a physician, was even more a philosopher, . . . having experimented upon himself in testing the pathogenetic properties of drugs to a greater extent than any previous physician."

The author, after going into the subject of the general demoralization of trade, and the cheating, fraud, and adulteration with which the world is filled, gives this simple and happy solution of the problem: "The true remedy"—he has just been quoting two pages from Henry Ward Beecher on the adulteration of paints, coffee, and liquor—"obviously consists in diversity of mental occupation, and in especially avoiding prolonged mental concentration on single objects and pursuits." Columbus discovered America; but that was trivial. How wonderfully easy, how sublimely simple! Let us give our milkman a copy of the Essay on Mental Hygiene, and advise our too concentrated grocer to visit the theatre,—or some fashionable watering-place, should the season be hot,—to keep him from sanding the sugar.

In Chapter V. the author extols poverty and discourses upon prayer, which latter he considers "a valuable specific to mental hygiene," causing a healthy tone of mind in him who prays, though by no means altering the regular course of things. "These doctrines," he says, "it is objected, are unscriptural: undoubtedly so much the worse is it for Scripture;" after which appropriately follows a chapter on marriage, its abuses and wrongs, equally liberal and free,—freer, indeed, it seems to us, than even the average sentiment of the day. However, like all reformers, he has his remedy. "The primary remedy for these evils, then, is knowledge,—knowledge of ourselves." This is hardly a paraphrase, and not included by him in quotation-marks; and yet the same remark has always been attributed to an ancient Greek, with whose sayings Dr. Gorton is probably unfamiliar. This is so often the way with supposed discoveries and new remedies: they turn out to be old as the hills. Know thyself—not Emerson, or George Eliot, or Maudsley, or James Parton, but thyself—is the unsuspected kernel of the Essay on the Principles of Mental Hygiene. E. W. W.

GLEANINGS FROM OUR EXCHANGES.

THE PREVENTION OF LOSS OF BLOOD IN OPERATIONS. —Considerable interest has been excited among surgeons on the Continent, and also in this country, by the description, by Professor Esmarch, of Kiel, of a proceeding for preventing the loss of blood which often interferes seriously both with the performance and with the success of operations. The proceeding consists in pressing the blood out of the part to be operated on, and preventing its return until the operation is completed.

A clinical lecture of Professor Esmarch lies before

us, in which he gives a graphic description of an operation in which his plan was applied with complete success. The case was one of extensive necrosis of both tibiæ. While the patient was being brought under the influence of chloroform, a bandage of india-rubber webbing was applied tightly round each leg, from the toes to above the knee. Immediately above the bandage, a piece of india-rubber tubing was drawn firmly four or five times round the thigh, and its ends were secured together by hook and chains. This being done, the elastic bandage was removed from the leg, which was found to be quite exsanguine,—in fact, like the leg of a subject on the dissecting-table. The operation for removing the sequester was then performed. So utterly bloodless was it—so entirely free from the oozing which often requires the aid of an assistant to clean the wound before the surgeon can proceed with his operation—that Dr. Esmarch was able to dispense altogether with the aid of an assistant. In fact, his ordinary assistant, Dr. Petersen, was at the same time operating in a similar manner on the other leg of the same patient; Dr. Esmarch having decided that, as he could save the patient's blood, he would also avoid subjecting him to two operations at different times, and thus spare him the tedium of two processes of convalescence. The operation having been completed and the wounds dressed with plugs of amadou and antiseptic applications (Dr. Esmarch being apparently a follower of Prof. Lister's doctrines), the caoutchouc tube was removed, and the blood allowed to re-enter the leg. There was no hemorrhage,—the whole amount of blood lost during the operation being about a teaspoonful from the bone. The subsequent progress of the case was most satisfactory: the healing process proceeded so rapidly that the patient was enabled to leave the hospital, at his own request, on the twenty-first day after the operation.

The plan here described has been employed by Prof. Esmarch in eighty-seven cases of operation, from the beginning of the present year to August 15. Of these, twenty-one were cases of amputation and disarticulation (including six amputations of the thigh, eight of the leg, and one disarticulation of the humerus); eight were cases of excision, thirteen of removal of necrosed bone, five of operation for the removal of tumors. Of the eighty-seven patients, four only died. The amputation-wounds generally healed by the first intention, with scarcely any traumatic fever. In no instance have there been any indications of local disturbance of the circulation as the result of the compression.

The method described by Dr. Esmarch is obviously applicable only, as he states, to operations on the extremities, and on the penis and scrotum; in other regions of the body its application in the manner described is obviously impossible. Yet Dr. Esmarch makes a very ingenious suggestion for its application in operations on the head, neck, or trunk, remarking at the same time that the idea is one the possibility of carrying which into practice requires to be tested by experiment. It is that, as a preliminary to the operation, the elastic tubing should be applied around one or more of the limbs, so as to retain a store of blood in them, which might be allowed to re-enter the circulation from one limb after the other, if the patient showed symptoms of being exhausted by the hemorrhage attending the operation.

One caution he gives, and it is an important one. When infectious material is present in the limb to be operated on, the elastic bandage must not be applied, lest the poisonous matter should be drawn into the general circulation. In such cases, the limb is to be raised so as to empty it of blood as much as possible; and then the compressing ring of elastic tubing is to be applied.

The method described by Esmarch has been tested

and found efficient by Prof. Billroth, of Vienna, Dr. Menzel, of Trieste, and the surgeons of St. Thomas's Hospital in London. Its simplicity, and the successful results which have hitherto attended its application, render it worthy the attention of surgeons. In cases where the surgeon has to operate in circumstances where he cannot obtain efficient assistance, it must be of great value.—*British Medical Journal*.

CROTON-CHLORAL HYDRAT.—The profession and the public are chiefly indebted to Dr. Oscar Liebreich for the introduction of chloral hydrate; and this obligation is further increased by the addition of croton-chloral hydrat, which will doubtless prove an equally valuable therapeutic agent. It is of the greatest service in cases of nerve-pain. Every sufferer from neuralgia is anxious to obtain speedy relief from pain: this may be obtained by taking croton-chloral hydrat, and then the antecedent causes of the neuralgia may afterwards be inquired into and treated accordingly. The following cases are interesting, as showing the immediate relief from pain that this drug affords:

A. suffered from facial neuralgia of a most severe character; it affected her hearing and eyesight. She could not rest or take food. She took one grain of croton-chloral hydrat every hour. In three hours she was considerably better. After taking three more doses, she was entirely free from pain.

B. suffered much from facial neuralgia dependent on decayed teeth, and had not been able to take food or sleep for three days. She was ordered croton-chloral hydrat in grain doses every hour, and obtained great relief after two doses. Six doses removed the pain completely. She slept that night.

C. This patient suffered from concussion of the spine caused by a railway-accident some years ago. She has had every variety of treatment for the pain she suffers in the spine and the nerves proceeding therefrom. She took potassium bromide, gr. xx, and croton-chloral hydrat, gr. i, three times a day, with marked relief and no bad symptoms.

E. This is a young dyspeptic and neuralgic patient, and suffers greatly from dysmenorrhœa. She took two-grain doses when the paroxysms of pain came on, with marked relief.

F. has been under treatment for various neuralgiæ for some years. She has had, at one time or another, almost every external and internal therapeutic agent in the Pharmacopœia,—strychnia, iron, quinine, ammonium chloride, aconite, belladonna, iodine, bromine, blisters, hypodermic injections, galvanism, together with baths and other hygienic appliances, including change of air. In this case, two-grain doses of croton-chloral hydrat every hour afforded more speedy relief from pain than any of the above remedies. After taking eight grains, she was almost free from pain.

In thirteen patients who have taken croton-chloral hydrat, not a single bad symptom has been observed. In grain doses, it relieves pain quickly, causes natural sleep, no subsequent headache or furred tongue. In several cases it acted as a gentle laxative.—*Benson Baker, in British Medical Journal, October 25.*

MEDICAL USES OF CHARCOAL.—A lecture was recently delivered before the Society of Arts, in London, by Mr. W. E. Newton, in which he attributed various virtues to peat and other vegetable charcoal. He stated that in the form of powder, put upon poultices, peat charcoal had been most beneficially employed in some of the London hospitals, especially in cases of offensive sores. It absorbed the putrid effluvia, and was of great benefit in cancers, etc. In many cases, when taken internally, it was productive of good effects in those troubled with disordered stomachs, such as heart-burn, sick headache, palpitation of the heart, and giddiness. In all

diseases of the chest, sore throats, diphtheria, or bronchial affections, peat charcoal has been found very useful. In France, a scientific commission, appointed by government to investigate this subject, has reported very favorably in regard to the usefulness of this substance for a great number of purposes. A minute quantity of peat charcoal, in powder, boiled with some American corn-starch and milk, has been given with marked success in London for dysentery.—*Druggist's Circular*.

INTUSSUSCEPTION IN CHILDREN (*Edinburgh Medical Journal*, September, 1873).—Dr. J. O. Affleck believes the following facts to have been satisfactorily established: 1. That the seat of intussusception in young infants is almost always some portion of the large intestine, usually the neighborhood of the ileo-cæcal valve. 2. That while a cure by the spontaneous reduction and replacement of the invaginated bowel seems occasionally to be effected, yet that that process of spontaneous cure by sloughing of the bowel and subsequent cicatrization, which is sometimes observed in adults and in children beyond one year, appears almost never to take place in young infants. 3. That in them the morbid phenomena following intussusception advance with great rapidity and fatality, and that treatment to be effectual must be prompt and active.

Dr. Affleck details two cases occurring in his own practice, one of which terminated in death, the other in recovery. In the former the initial symptoms were merely slight vomiting and gastric pain, and were not succeeded by urgent symptoms for forty-eight hours, when a discharge of blood and bloody mucus took place from the rectum. Enemata of warm water, inflation, and metallic mercury, were tried unsuccessfully. In the second case all the symptoms came on with great rapidity, and the bloody discharge occurred within a few hours of the commencement of the trouble. Enemata were quickly and forcibly expelled in this case, but inflation was attended with almost immediate success. There was distinct evidence of the sudden yielding of the obstruction, followed by cessation of the symptoms of disturbance, restoration of the normal functions of the bowel, and speedy recovery.

TREATMENT OF GLANDULAR AFFECTIONS (*Edinburgh Medical Journal*, August, 1873).—Dr. F. Page Atkinson, after alluding to the uncertainty which prevails in the treatment of glandular affections, asserts that, according to his own experience, and speaking generally, acute glandular inflammation requires the administration internally of the effervescent citrate of potash, and the application locally of a sedative, or the tincture of iodine.

As regards *quinsy*, he says he can predict with certainty that any patient will be quite well and able to resume his duties on the fourth day, and that he has never had a single case which went on to suppuration, when the following plan of treatment was observed: bicarbonate of potash, 20 grains; compound tincture of guaiacum, 30 minims; compound tragacanth powder, q. s.; in one ounce of water; and 15 grains of citric acid in half an ounce of water. To be taken in a state of effervescence three or four times daily. Twenty-five minims of the tincture of iodine in an ounce of water to be used as a gargle three or four times daily; three or four glasses of port-wine in the twenty-four hours, and as much beef-tea as the patient can take. The throat should be left uncovered, and poultices, steam-inhalations, and the use of purgatives should be particularly avoided.

When suppuration has already commenced, order simply the iodine gargle, the port-wine and beef-tea, and omit all internal medicines.

In inflammation of the breast, he gives a similar

effervescent mixture, containing nitre and ammonia, and applies an ointment consisting of three parts ext. belladonnæ and one of ung. iodinii. In orchitis, he recommends a lotion of fifteen minims of laudanum and fifteen minims of the tincture of belladonna to the ounce of water; and in this disease, as well as in bubo, parotitis, etc., he employs the citrate of potash mixture, with slight variations.

MISCELLANY.

HOW SOON CAN A WOMAN CONCEIVE AFTER PARTURITION?—The editor of *The Clinic* (November 8) endorses the following communication of Dr. W. J. Bertollett:

"At 7.45 o'clock A.M. of December 12, 1869, I delivered Mrs. M. of a full-grown child, female, that lived but a few hours.

"On the 4th day of October, 1870, I was again called in the early part of the night to this same patient in labor, and at 12.30 A.M., in less than one hour after entering the house, delivered her of a full-grown healthy male child, weighing eight and a half pounds, that lived to die of an acute disease one and a half years thereafter.

"In this case the interval was 295 days and 4½ hours, so that, allowing the period of gestation to be 273 to 280 days, it is fair to concede conception to have taken place at from fifteen to twenty-two days after delivery."

Any one who visits Chilwell, England, can read in the cemetery the following epitaph:

"Here lies me and my three daughters,
Brought here by using Seidlitz waters.
If we had stuck to Epsom salts,
We wouldn't have been in these here vaults."

—*Medical and Surgical Reporter*.

INDESTRUCTIBLE PUTTY.—Boil four pounds of brown umber in seven pounds of linseed oil for two hours; stir in two ounces of wax; take from the fire and mix in five and a half pounds of chalk and eleven pounds of white lead, and incorporate thoroughly. The latter operation is quite essential.—*Druggist's Circular*.

A PASTE FROM RICE FLOUR.—Dissolve one hundred and twenty grains of rice flour and twenty grains of gelatin in two ounces of water, heating and stirring continually until it becomes thick and glassy.—*Journal of Applied Chemistry*.

THE CAUSE OF KLEPTOMANIA.—The most ingenious theory ever proffered, perhaps, in explanation of this peculiar diathesis was that lately stated in *New Jersey*: "because the individual had been vaccinated with virus from a hooking cow."—*The Clinic*.

CURE FOR CORNS.—A mixture of equal parts of glycerin and carbolic acid, applied with a camel's-hair pencil, is an excellent remedy for these painful companions.—*Journal of Applied Chemistry*.

WE see by a recent exchange that Dr. Hermann Beigel has just translated Dr. Marion Sims's work on Ovariectomy into the German language.

IN the seventeenth century a law was in force in England that all women, of whatever age, rank, profession, or degree, whether virgins, wives, or widows, that should impose upon, seduce, and betray into matrimony any of his Majesty's male subjects by scents, paints, cosmetics, washes, artificial teeth, false hair, Spanish wool, iron stays, hoops, high-heeled shoes, or bolstered hips, should incur the penalty of the law, and that the marriage should stand null and void. It is said Mr. Gladstone, to increase his popularity, is about to have this law revived.—*Druggist's Circular*.

PERPETUAL PASTE.—Dissolve a teaspoonful of alum in a quart of water. When cold, stir in as much flour as will give it the consistency of thick cream, being particular to beat up all the lumps; stir in as much powdered resin as will lie on a dime, and throw in half a dozen cloves to give it a pleasant odor. Have on the fire a teacup of boiling water; pour the flour mixture into it, stirring well at the time. In a few minutes it will be of the consistency of mush. Pour it into an earthen or china vessel; let it cool; lay a cover on, and put it in a cool place. When needed for use, take out a portion and soften it with warm water. Paste thus made will last twelve months. It is better than gum, as it does not gloss the paper, and can be written on.—*Boston Journal of Chemistry*.

PROF. HYRTL has announced his purpose of resigning his chair in Vienna next spring. As, according to the *Allgem. Wien. Med. Zeitung*, the attendance of students on the Viennese school has declined to the amount of three hundred since the retirement of Skoda and the death of Oppolzer, it seems probable that the faculty will attempt to retain Prof. Hyrtl, one of their most noted members and popular lecturers. Prof. Hyrtl is just now probably in the acme of his powers.

PURGATIVE MIXTURE OF VIENNA.—The *Journal de Pharmacie et de Chimie* gives the following:

Manna,	66 grammes.
Senna,	10 "
Cream of tartar,	4 "
Coriander, raisins, āā	2 "
Water,	320 "

Boil until the water is reduced to 190 grammes. Take before breakfast.

AN instance of the ludicrous results which sometimes follow the use of words not generally known in addressing patients is given by Dr. Filippi in a recent number of *L'Imparziale*. A student, he says, was in his presence one day examining a patient in hospital, and asked him, "Are you addicted to onanism?" (*Ti dai all' onanismo?*) "No, sir," was the reply; "I am a shoemaker."—*The Clinic*.

VANADIUM INK.—One part of pyrogallie acid, three parts of finely pulverized and sifted gum arabic, and three parts of neutral vanadate of ammonia, are triturated in a porcelain mortar with a suitable quantity of cold rain-water. In a short time an excellent ink is formed, that flows freely and has a deep-black color.—*Journal of Applied Chemistry*.

WHITE INK, for writing upon blue paper (like that used for Seidlitz powders), may be made of a solution of potassic carbonate, simple syrup, and mucilage. This ink can be used with a steel pen, and cannot be extinguished, even by dilute sulphuric acid. It can be used on but one side of the paper.—*Journal of Applied Chemistry*.

REMEMBER that a raw egg will clear your throat of fish-bones. Put one in a little hot wine, add some sugar, and the fish-bones will slip down all the easier. P.S.—You can take the egg, wine, and sugar, anyhow. They're good as a preventive; and you don't know what moment you may get a fish-bone in your throat.—*Druggist's Circular*.

BLACK BRANDING-INK.—Triturate together one part of pine soot and two parts of Prussian blue with a little glycerin; then add three parts of gum arabic and sufficient glycerin to form a suitable paste.—*Boston Journal of Chemistry*.

DR. ADDINELL HEWSON, of the Pennsylvania Hospital staff, on his return to active professional life, after a long sojourn in Europe, was the recipient of a complimentary dinner from his colleagues and other prominent members of the profession. The affair passed off most pleasantly.

THE next conversational meeting of the Philadelphia County Medical Society will be held, Wednesday, November 26, at 8 o'clock P.M., at the Hall of the College of Physicians. The regular physicians and students in the city are always welcome.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 10, 1873, TO NOVEMBER 17, 1873, INCLUSIVE.

HASSON, A. B., SURGEON.—Granted leave of absence for (20) twenty days, provided he makes satisfactory arrangements to supply medical attendance during his absence. S. O. 59, Headquarters Military Division of the Atlantic, November 12, 1873.

McKEE, J. C., SURGEON.—To report to the Commanding Officer of the Presidio of San Francisco, to relieve Assistant-Surgeon De Witt of his duties at that post. S. O. 130, Headquarters Department of California, October 30, 1873.

WOLVERTON, W. D., ASSISTANT-SURGEON.—To report to the Commanding General Department of the South, for assignment to duty. S. O. 227, War Department, A. G. O., November 14, 1873.

GREENLEAF, CHARLES R., ASSISTANT-SURGEON.—To report to the Commanding General Department of the South, for assignment to duty. S. O. 227, War Department, A. G. O., November 14, 1873.

CALDWELL, D. G., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, and to report in person to the Commanding General Department of Texas, for assignment to duty. S. O. 227, War Department, A. G. O., November 14, 1873.

TAYLOR, M. K., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, and to report in person to the Commanding General Department of Texas, for assignment to duty. S. O. 227, War Department, A. G. O., November 14, 1873.

DE WITT, CALVIN, ASSISTANT-SURGEON.—On being relieved by Surgeon McKee, will comply with Paragraph 9, S. O. 192, c. s., from the Adjutant-General's Office. S. O. 130, Headquarters Department of California, October 30, 1873.

PATZKI, J. H., ASSISTANT-SURGEON.—To report in person to the Commanding General Department of the Platte, for assignment to duty. S. O. 227, War Department, A. G. O., November 14, 1873.

MATTHEWS, WASHINGTON, ASSISTANT-SURGEON.—Assigned to duty at David's Island, New York Harbor. S. O. 59, Headquarters Military Division of the Atlantic, November 12, 1873.

SATURDAY, NOVEMBER 29, 1873.

ORIGINAL LECTURES.

MEANING AND HISTORY OF LARYNGOSCOPY AND KINDRED METHODS OF EXAMINATION.

A Lecture delivered at the University Medical College, New York,

BY LOUIS ELSBERG, M.D.,

Professor of Laryngology and Diseases of the Throat.

GENTLEMEN,—Among the means of making ourselves acquainted with diseases of the throat, laryngoscopy and kindred methods of exploration are by far the most important. We must to-day inquire into the meaning and history of these methods.

Laryngoscopy (*larynx*, and *scopeo*, to "view,") is a term used to designate the method of rendering the interior of the larynx accessible to view in the living subject.

Rhinology (*rhin*, the "nose," and *scopeo*) denotes the method of inspecting the interior of the nose and the pharyngo-nasal space. It is divided into *pharyngeal rhinology*, the method of inspecting these parts through the mouth, and *anterior rhinology*, the method of looking into the nostrils.

Œsophagoscopy is the method of dilating and inspecting the interior of the œsophagus.

Tracheoscopy is the mode of inspecting as much of the air-passages below the larynx as possible; and by *pertracheal laryngoscopy* and *tracheoscopy* are meant laryngoscopy and tracheoscopy practised through an opening into the trachea from without.

The principle upon which laryngoscopy is founded is very simple. It is that a small mirror, previously warmed to prevent its being tarnished by the breath, may, by means of a long handle, be introduced into the fauces, and so held there that rays of light entering through the widely-open mouth impinge against it and illuminate the organs to be examined, while the image of those organs is reflected into the eye of the observer. The theory is elucidated at a glance by a diagram representing some rays of light emanating in a horizontal direction from a luminous point, to impinge upon a plane surface directed obliquely downward, and to be reflected in accordance with the optical law that the angle of reflection is equal to the angle of incidence. It is on the same principle as that of which ladies avail themselves when they place in an oblique direction, outside of an upper front window, a mirror which reflects the image of the street and front door into the room, so that they can see who passes and who rings the bell, and be "at home" or "out," as they choose to instruct the servant, without any danger of being themselves seen. I am in the habit of explaining this principle still more familiarly by holding up my hand vertically, with closely-approximated fingers, and the thumb behind, so that the observer can see my thumb-nail

only by means of a mirror held above in an oblique direction.

On looking directly into a person's throat, we can see only in a horizontal direction; by means of the little mirror we can look "round the corner," or in a vertical direction, either downward into the larynx or upward into the pharyngo-nasal space. The parts brought under the control of the eye by laryngoscopy, and which otherwise are either completely invisible or seen only with difficulty and in rare instances, are the postero-inferior portion (base or root) of the tongue, the glossal insertion and posterior surface of the palato-glossal fold,* the glosso-hyoid folds, the posterior surface and portions of the tonsils, the infra-tonsillar glands, the supra-tonsillar glands, the glosso-epiglottic ligament or frænum, the glosso-epiglottic sinuses or valliculæ, the palato-pharyngeal fold, the pharyngo-epiglottic fold, the hyo-epiglottic ligaments, the capitulum of the hyoid bone, the epiglottis, the ary-epiglottic folds, the corniculum Wrisbergii or projecting extremity of the cuneiform cartilages, the nodules of Santorini or supra-arytenoid cartilages, the arytenoid cartilages, the inter-arytenoid fold, the posterior wall of the pharynx down to its contact with the arytenoid and cricoid cartilages, the pharyngo-laryngeal or pyriform sinuses, the upper cavity of the larynx with all its boundaries and contents, as the epiglottic cushions, central and lateral gutters, ventricular folds, entrances to the ventricles of Morgagni, the upper surfaces and free edges of the vocal bands, the vocal processes (the columella of Morgagni's gland, when sufficiently developed), and the anterior wall of the lower cavity of the larynx. The posterior part of the mucous membrane of the glottis, and portions of the lower cavity of the larynx, can usually not at all or but very imperfectly be seen.

Pharyngeal rhinology reveals the posterior surface of the soft palate, the upper posterior wall of the pharynx in its whole extent, with its tonsil-like glands, the orifices of the Eustachian tubes, the Rosenmüller's fossæ, the posterior nasal septum, the posterior nares, the mucous membrane covering the turbinated processes of the ethmoid bone, the mucous membrane of the posterior portion of the turbinated bone; in short, the whole pharyngo-nasal space, with its orifices, projections, etc. Under favorable circumstances, the eye reaches the covering mucous membrane of the nasal bones and of the plate of the ethmoid.

Anterior rhinology shows the interior of the nostrils, the anterior portion of the turbinated bone, a portion of the middle concha, and a portion of the floor and septum of the nasal cavity. Under very favorable circumstances, the posterior wall of the pharynx, and even the orifices of the Eustachian tubes, have been seen by Voltolini; while Czermak

* I adopt for the anterior and posterior half-arches the appellation proposed by Dr. Harrison Allen (see Transactions of the American Medical Association for 1872). The improved nomenclature in other respects, as, for instance, ary-epiglottic folds, ventricular folds, vocal bands, etc., I introduced a number of years ago. See, mainly, Transactions of the New York Academy of Medicine, vol. ii., part xii., 1863; Laryngoscopy, Medication, New York, Wood & Co., 1864; Transactions of the American Medical Association, 1865; and articles in various periodical publications.

has succeeded in recognizing in the dead subject the nasal opening of the lachrymo-nasal duct.

By œsophagoscopy we may see the upper portion of the interior of the œsophagus.

Tracheoscopy shows the anterior wall, and sometimes the lateral walls, of the trachea for a more or less considerable distance down,—under favorable circumstances, down to the bifurcation, and even the interior of the right bronchus.

Pertracheal laryngoscopy shows the inferior surface of the glottis, and various portions of the lower cavity of the larynx,—sometimes, also, portions of the upper cavity; and pertracheal tracheoscopy, portions of the walls of the trachea not otherwise visible.

In the practical application of these methods obstacles present themselves which we shall discuss in detail in subsequent lectures. They can usually be overcome by skill, patience, and perseverance. At first it was supposed that very few persons could bear the mirror in the mouth; but it was soon found, as Czermak had predicted it would be, that the difficulty arose chiefly from the inexperience and awkwardness of the investigator. The number of patients in whom the larynx and adjacent structures cannot be brought into view diminishes with increasing experience and ability of the examiner. The percentage, at first stated to be very high, gradually fell to twenty-five, as I reported it to be ten years ago: it has now, with experienced laryngologists, become so low that I am bound to say that a case of non-success is of quite rare and exceptional occurrence.

The value of the methods has long been, and by many still is, under-estimated; on the other hand, a few one-sided enthusiasts have gone to the other extreme. In the first place, the mere possession and use of the instruments do not enable every one to derive much benefit from them; for after we can see we do not necessarily know: we must be able to interpret what we see. Furthermore, as to diseases of the larynx, the mistake has been made of supposing that the laryngoscope is to take the place of all other means of recognizing pathological conditions; but, gentlemen, the laryngoscope is but *one* of the diagnostic means with which I shall endeavor to make you familiar, although in point of fact it is, as I said at the beginning of the lecture, the most important one of all. To ignore its value—as is done even to-day by many physicians—is a still greater mistake than to overestimate it, for, “whereas before we saw not, now we see.” In the practitioner’s encounter with laryngeal disease its non-employment or employment makes all the difference that exists between the condition of one who endeavors to grope his way in the gloom of the darkest night, and that of one who walks securely under the light of the mid-day sun.

In pursuing the history of any important discovery or invention, we cannot fail to be struck with the steady but gradual march of improvement. Although the discoveries of a Galileo, a Newton, or a Columbus, of a Jenner, a Harvey, or a Bichat, and the inventions of a Gutenberg, a Fulton, or a Davy, of a Chamberlain, a Laennec, or a Helmholtz,

may, when their practical results are worked out, burst like a lightning-flash upon the world at large, the patient student finds the road leading to them covered with forerunners and prophets. Perchance he finds a long record of vain endeavors and fruitless labors, of partial or unrecognized success. He finds how near many a man has been to a grand invention “without making it;” how many times a principle discovered has been allowed to slumber long before being applied to what afterwards seem obvious practical uses; and how often an improvement demonstrated has fallen into oblivion until rediscovered or revived. All this but shows that human knowledge progresses not by sudden leaps, but with continuous, measured steps, and not in a straight line, but in a spiral.

Laryngoscopy forms no exception to the rule here implied. Dentists seem to have used a little mirror in the mouth for their purposes from time immemorial; but who first conceived the idea of so introducing a mirror into the fauces as to reflect and permit inspection of the interior of the larynx, it is impossible to say. Paul of Ægina described, under the name of *glossotochus*, an instrument for inspecting the mouth and pharynx,—possibly the same or nearly the same as the *speculum oris* described and figured by Ambroise Paré (Op., Lyon, 1641, p. 190), Fabricius Hildanus (Op., Francofurti ad Mœnum, 1646, p. 1042), Scultetus (Armentarium Chirurgicum, 1655), and others.* More than a hundred and twenty-five years ago, Levret, of Paris, employed a mirror in the exploration of the fauces, and successfully used it in operating on polypus in the throat, as the extension of nasal polypus.† More than sixty years ago, Bozzini, of Frankfort-on-the-Main, in a pamphlet on *The Illumination of the Cavities and Internal Spaces of the Living Animal Body*,‡ described what he calls a very simple instrument for examining the throat, but what in its entirety was really so complicated and cumbrous an apparatus that it was soon forgotten. To both Levret and Bozzini I shall refer again when speaking of the history of rhinoscopy.

Nearly fifty years ago, Cagniard de Latour, the celebrated physicist, endeavored to behold the living vocal bands in working-order by introducing a small mirror into the back of the throat; and, although he did not succeed in seeing more than the epiglottis, he was, so far as is at present known, the first who practised laryngoscopy.§

* For the references mentioned I am indebted to Sir George Duncan Gibb. See his various publications on the subject, but especially *The Laryngoscopy in Diseases of the Throat*, third edition, London, 1868, p. 3.

† *Observations sur la Cure radicale de plusieurs Polypes de la Matrice, de la Gorge et du Nez, opérée par de nouveaux Moyens inventés par M. Levret, Maître en Chirurgie, etc.* Paris, Delaguerre, 1749, pp. 106 and 500, plates 6.

‡ *Der Lichtleiter oder Beschreibung einer einfachen Vorrichtung und ihrer Anwendung zur Erleuchtung innerer Höhlen und Zwischenräume des lebenden animalischen Körpers.* Von Philipp Bozzini. Weimar, 1807, pp. 6 and 23, plates 4.

§ “M. Cagniard de Latour s’est ensuite introduit dans le fond de l’arrière-gorge un petit miroir, espérant qu’à l’aide des rayons solaires et d’un second miroir, il pourrait apercevoir l’épiglotte et même la glotte; mais par l’emploi de ces moyens il n’a pu découvrir que l’épiglotte, et d’une manière imparfaite.”—*Journal de l’Institut*, No. 225, quoted in *Physiologie de la Voix et de la Parole*, par le Dr. Edouard Fournié, Paris, Adrien Delahaye, 1866, p. 352. Fournié, in his “*Etude pratique sur le Laryngoscope*,” etc., Paris, 1863, p. 8, gives to Gerdy the credit of having been the first to examine the throat with the mirror; but that is a mistake.

A few years later, Senn, of Geneva, tried in the same manner, but with no better success, to inspect the interior of the larynx of a child on whom he was about to perform tracheotomy. He ascribed his failure to the small size of his mirror; while Morell Mackenzie* thinks it arose really from the non-illumination of the larynx. Senn insisted, however, upon the possibility and value of the practical employment of the mirror at least in adults, and recommended its use in suitable cases.†

On the 18th of March, 1829, Benjamin Guy Babington, of London, at a meeting of the Hunterian Society, exhibited an instrument which he proposed to call a *glottiscope*. "It consisted of an oblong piece of looking-glass, set in silver wire, with a long shank. The reflecting portion is placed against the palate, whilst the tongue is held down by a spatula, when the epiglottis and upper part of the larynx become visible in the glass. A strong light is required; and the instrument should be dipped in water, so as to have a film of the fluid upon it when used, or the halitus of the breath renders it cloudy."‡ It is claimed§ that Dr. Babington invented and employed this instrument without having any knowledge of the previous labors in the same direction, and he is called the "real discoverer," the "original inventor," etc.

On the other hand, it has been said|| that he could not well have obtained a view of the vocal cords, much less of parts beyond, because, instead of elevating, he depressed the epiglottis; and he himself, more recently, has declared "that he had seen ulceration on the epiglottis, but he confessed that he did not contemplate looking through the glottis."¶

In 1832, Selligues, a mechanician of Paris, himself a patient, independently of his predecessors, devised a laryngeal mirror attached to the extremity of a tube, the light being thrown upon it through another tube. With this apparatus Beninati is said to have obtained a view of the whole interior of the larynx.** After the same pattern Sanson made a laryngeal speculum for Drs. Trousseau and Belloc in 1836; but Trousseau himself is said to have stated that he had never employed it,†† and in their book it is by no means favorably spoken of.‡‡

* Description of the First Laryngoscope, etc.,—London Lancet (American edition), July, 1864, p. 412.

† "Je fis construire un petit miroir pour le porter au fond du pharynx et chercher à voir la partie supérieure du larynx et de la glotte; mais je renonçai à son emploi, vu la petitesse de l'instrument. Toutefois je crois que ce moyen peut être employé," etc. The case reported by Senn occurred in the year 1827, and was brought before the Paris Academy by Dupuytren and Duméril on the 10th of December of that year, but the account of the attempted laryngoscopy was not published until two years later, viz., in the Journal des Progrès, 1829, p. 231; this is doubtless the reason why Verneuil fixes its date as 1829 in his article on the history of laryngoscopy in the Gazette hebdomadaire de Médecine et de Chirurgie, Paris, 1863, x., No. 13.

‡‡ "Cet instrument, dont il ne faut point s'exagérer l'utilité, est d'une ap-

plication très-difficile, et il n'est guère plus d'un malade sur dix qui puisse en supporter l'introduction. Il est une difficulté qui à elle seule suffirait pour dégoûter à jamais de se servir de cet instrument, c'est la présence de l'épiglote. Cet opercule à une grande largeur, et il recouvre si exactement la partie supérieure du larynx qu'il empêche totalement que la représentation de cet organe puisse être répétée dans le miroir; et de plus, la lumière projetée sur l'instrument tombe directement et nécessairement sur la face linguale de l'épiglote, et l'ombre de celle-ci couvre précisément le larynx et le dérobe complètement à la vue." Trousseau et Belloc, Traité pratique de la Phthisie laryngée, de la Laryngite chronique, et des Maladies de la Voix, Paris, 1837, p. 179.

In 1840, Liston, of London, speaks of the laryngeal mirror in connection with "ulcerated glottis."|||

In 1844, Warden, of London, invented a prismatic speculum with which he succeeded in seeing the interior of the larynx.¶¶

In 1846, Avery, of London, invented an apparatus for the examination of the larynx, consisting of an illuminating lamp and mirror, both supported by one stem, which was to be held between the operator's teeth, and a tube with a small mirror placed at one end at an angle of forty-five degrees, which was to be introduced into the patient's mouth.***

Eyrel, of Vienna, a music-teacher, claims to have used, also in 1846, for the same purpose, a rectangular glass prism fastened to one end of a wooden stem, while a mirror was fastened to the other.†††

Jacobi, of New York, had an oval glass mirror made in 1854, one and a half inches long and one inch broad, and attached to a flexible metal handle, with which he states he "succeeded in seeing the interior of the larynx of a gentleman who, having constitutional syphilis, had long attributed a morbid sensation in the region of the larynx to the probable presence of syphilitic ulcerations; but repeated inspection showed that there were no such local lesions."††††

Garcia, a Spaniard, a *maestro* of singing (brother of Madame Malibran), while residing in Paris and London, employed the laryngeal mirror, principally on himself, but also on other healthy persons, in order to study the mechanism of the human voice, and his researches were read before the Royal Society

plique très-difficile, et il n'est guère plus d'un malade sur dix qui puisse en supporter l'introduction. Il est une difficulté qui à elle seule suffirait pour dégoûter à jamais de se servir de cet instrument, c'est la présence de l'épiglote. Cet opercule à une grande largeur, et il recouvre si exactement la partie supérieure du larynx qu'il empêche totalement que la représentation de cet organe puisse être répétée dans le miroir; et de plus, la lumière projetée sur l'instrument tombe directement et nécessairement sur la face linguale de l'épiglote, et l'ombre de celle-ci couvre précisément le larynx et le dérobe complètement à la vue." §§ "A l'extrémité d'une tige de bois ou de balaine cylindrique est placé un miroir de la largeur d'une pièce de deux francs, dont on peut faire varier l'inclinaison à l'aide d'une vis de rappel. Par ce moyen on peut reconnaître facilement les inflammations, engorgements ou ulcérations que l'on ne pouvait que soupçonner, à l'extrémité postérieure des fosses nasales, au larynx et dans quelques parties du pharynx. L'usage de cet instrument, très-facile d'ailleurs, est d'une utilité incontestable." Comptes-Rendus des Travaux de la Société de Médecine de Lyon, depuis le 1^{er} Juillet, 1836, jusqu'au 30 Juin, 1838, sous la Présidence de M. Janson, par L. A. Rouquier, Lyon, 1840, p. 62.

|| "A view of the part may sometimes be obtained by means of a speculum, such a glass as is used by dentists, on a long stalk, previously dipped into hot water, introduced with its reflecting surface downward and carried well into the fauces." Robert Liston, Practical Surgery. With Fifty Engravings on Wood. Third edition, London, 1840, p. 417.

¶¶ "The epiglottis was immediately seen, but it was only when efforts to swallow were made that the arytenoid cartilages and glottis were raised out of concealment and brought brilliantly to show their picture in the reflecting face of the prism."—A. Warden, London Medical Gazette, May 24, 1844, vol. xxxiv. p. 256; London and Edinburgh Monthly Journal of Medical Science, vols. iv., v., 1844-1845,—more especially vol. v. p. 552; Windsor, *loc. cit.*

*** Avery had published no description of his instrument, but had shown it to many medical men of London. Vide Medical Times and Gazette, vol. ii., 1860, p. 111; Yearsley, Introduction to the Art of Laryngoscopy, London, 1862; Gibb, Diseases of the Throat and Windpipe, second edition, London, 1864, p. 443, etc.

††† Physiologie der menschlichen Tonbildung, nach den neuesten Forschungen gemeinfasslich dargestellt. Leipzig, 1860, p. 140.

†††† Verbal communication made to me some years ago.

of London on the 24th of May, 1855.* His manner of proceeding he describes as follows:

"It consists in placing a little mirror, fixed on a long handle suitably bent, in the throat of the person experimented on, against the soft palate and uvula. The party ought to turn himself towards the sun, so that the luminous rays falling on the little mirror may be reflected on the larynx."

For autolaryngoscopy, or examination of one's own larynx, he adds, "The little mirror is illuminated by means of a second one destined to receive the rays of the sun. The image is reflected first on the little mirror, whence it is sent to the external mirror."†

Cutter, of Woburn, in Massachusetts, invented in 1856 an instrument, at present in my possession, with which the laryngeal cavity and surrounding parts can be well inspected. It consists of a hollow cylinder of metal, open at one end, with a square opening at the bottom near the other extremity, in which a prismatic reflector is immovably fixed.

But, notwithstanding all that had thus been accomplished, laryngoscopic explorations remained only isolated experiments, not followed by important results as to practical medicine, until subsequent to the employment of a mirror for examining laryngeal diseases by Ludwig Türck, of Vienna, at the Vienna General Hospital, in the summer of 1857, and the investigations of Johann N. Czermak, of Cracow, but at the time residing in Vienna, during the winter of 1857-8. Indeed, it is probable that the whole of the interior of the larynx and trachea to its bifurcation had not really been *distinctly* seen in the living body previous to that time. In the spring of 1858, Czermak‡ and Türck§ pressed the subject upon the attention of the medical profession, and thence it became widely known and appreciated. From that time forward, laryngoscopy rapidly grew into favor and importance. Its literature has become quite extensive, and its history since the year 1858 is to be gathered from the practice of the laryngologists of to-day.

A lamentable circumstance in the history of laryngoscopy is the contest for credit as to "priority" waged by Drs. Türck and Czermak. They might safely have left the profession to judge between them, without indulgence in personal crimination and recrimination. The facts in the case are clearly before the medical world, and its verdict has accorded to each his due. The French Academy has rewarded both alike;|| and neither

should have profaned the mutual work by "claiming to be worthiest." Great credit is due to Türck for his careful experiments on the dead as well as on the living; for his consistent zeal and industry in medical laryngoscopy, both before and after he realized its full importance by Czermak's success; for his varied exertions to contrive instruments to facilitate and improve laryngoscopic diagnosis, medication, and surgical operations; for his investigation and application of the catoptric principles of the method; for the instructive pathological cases which he conscientiously examined, treated, and reported; and, finally, including all the preceding, for practically reviving laryngoscopy for medical purposes, and for the enduring monument that he has erected for himself in his "Clinic of the Diseases of the Larynx and Trachea,"—the most elaborate, able, and classical work published in the field of laryngology.¶

To Czermak great credit is due for his thorough and enthusiastic researches with the instruments first lent him by Türck; for having immediately perceived "that the laryngoscopic method would prove of great importance and of varied application;" for bringing it prominently to the notice of the profession at large; for popularizing it, by personal demonstrations all over Europe, having by dint of great perseverance acquired unequalled dexterity with it; for enlarging its sphere of usefulness in every respect, by improved apparatus and new applications; indeed, for being the great diffuser and teacher, through whose instrumentality mainly the laryngoscope has become one of the recognized, daily-used, practical appliances of medicine.

While most of those whose names are connected with its early history conceived the idea of the laryngoscope independently of each other, it is perfectly plain, from our historical sketch, that neither Prof. Czermak nor Prof. Türck could lay any claim to "priority" in the way of being a prime mover in the invention or discovery of laryngoscopy. In their labors for its advancement, however, both have been good and faithful workmen in the cause of science and humanity, and in the records of this

"Très-pen de temps après, dans l'hiver 1857-1858, M. Czermak se servit des miroirs laryngiens que lui avait prêtés M. Türck pour compléter les études physiologiques de M. Garcia, et pour observer le larynx dans la formation de certains sons, ceux des voyelles dites gutturales.

"M. Czermak a remis à l'Académie son Mémoire sur le laryngoscope en 1860, et il a démontré ses expériences devant la Commission. M. Türck a envoyé comme réclamation de priorité plusieurs publications, et plus tard un dernier Mémoire sur l'emploi du laryngoscope dans les maladies du larynx et du pharynx.

"La Commission n'a pas voulu entrer dans les discussions de priorité soulevées par MM. Türck et Czermak.

"La Commission a pensé que les recherches de M. Türck et celles de M. Czermak étaient celles qui avaient le plus contribué à faire de la laryngoscopie une méthode usuelle et susceptible de rendre des services dans le diagnostic des maladies du pharynx et du larynx; elle propose d'accorder à chacun de ces ingénieux observateurs une mention honorable.

"Sur la proposition de la Commission, l'Académie décide: 'Qu'une somme de douze cents francs sera jointe à chacune des deux Mentions accordées à MM. Türck et Czermak.'—Extrait du rapport sur les prix de médecine et de chirurgie, concours de 1860, Institut Impérial de France, Académie des Sciences, séance publique du lundi, 25 Mars, 1861.

"Klinik der Krankheiten des Kehlkopfes und der Luftröhre. Nebst einer Anleitung zum Gebrauche des Kehlkopfstachenspiegels und zur Lokalbehandlung der Kehlkopfkrankheiten. Von Dr. Ludwig Türck, A. O. Prof. an der Universität zu Wien, und Primararzt im K. K. Allgemeinen Krankenhause. Mit 260 dem Texte eingedruckten Holzschnitten und 1 Steindrucktafel." This great work, with a superb atlas, was published at the close of the year 1866, and its author died on the 25th of February, 1868.

* Observations on the Human Voice, by Manuel Garcia. Proceedings of the Royal Society, vol. vii. p. 399; Philosophical Magazine and Journal of Science, vol. x. p. 218; Gazette hebdomadaire, Nov. 16, 1855, No. 469; Schmidt's Jahrbücher, lxxix. p. 160, etc.

† Note addressed, January, 1861, by M. Garcia to M. Richard: *vide* Notice sur l'Invention du Laryngoscope, par Paulin Richard, Paris, 1861, p. 11.

‡ Wiener Medizinische Wochenschrift, No. 13, March 27, 1858, etc., etc. § Zeitschrift der Kaiserlich Königlich Gesellschaft der Aerzte zu Wien, No. 17, April 26, 1858 (report of meeting of April 9), etc., etc.

|| "Dans l'été de 1857 M. le docteur Türck, médecin en chef de l'hôpital général de Vienne, se livra à des recherches de laryngoscopie, dans le but de trouver une nouvelle méthode de diagnostic pour les maladies du larynx. La méthode de M. Türck, comme celle de M. Garcia, est fondée sur l'emploi d'un miroir laryngien. M. Türck apporta à ce miroir des modifications et lui fit subir des changements de forme, dans le but de rendre l'instrument plus facile à supporter par les malades, sur lesquels ce mode d'exploration produisit souvent des efforts de vomissements ou des sensations désagréables qui peuvent rendre très-difficile son usage. Comme M. Garcia, M. Türck se servait, dans ses premières recherches, de la lumière du soleil pour éclairer le miroir.

cause both will ever have "*une mention honorable*."*

As to pharyngeal rhinoscopy, I have already mentioned the names of Levret and Bozzini. Levret speaks of his *speculum oris* in several publications, and describes it in detail and figures it in his work on polypus. Consisting essentially of a metallic plate placed upon the tongue, the polished reflecting surface upward, it may occasionally have illuminated and well shown portions of the pharyngo-nasal space.†

With Bozzini's apparatus, which consisted mainly of two mirrors inclined towards each other under an angle of about forty-five degrees and fixed in a tube having a large opening immediately over their reflecting surfaces, one certainly could see behind the palate.‡

In 1838, Baumès, and in 1848, Avery, made rhinoscopic investigations.§ It has been stated by Czermak,|| Semeleder,¶ Türck,** Gibb,†† Mackenzie,‡‡ and others, that Wilde, of Dublin, had had the idea or had attempted to examine the orifice of the Eustachian tube from the oral cavity by the aid of a small mirror; but the very passage in Wilde's work upon which alone this statement can be based refers to a case of "complete occlusion of the naso-pharyngeal opening, owing to adhesion of the velum palati to the back and sides of the pharynx, the result of syphilitic ulceration," and the object of introducing, dentist-like, a small mirror into the mouth was not only not to practise rhinoscopy, but to confirm the thorough union of the parts, and, therefore, the obliteration of all communication between the oral and nasal cavities. §§

* Since writing the above, the sad news has reached us that Czermak's labors, too, are ended. He died September 16.

† "Il faut, pour opérer au fond de la gorge, se rendre maître de la mobilité de la machoire inférieure et de la langue; les divers *speculum oris* ou miroirs de la bouche qu'on nous a donnés jusqu'ici (voyez l'Arsenal de Sautet, table 11, fig. 4, etc., Ambroise Paré et le Dictionnaire ci-dessus cité, tome 3, planche 11, fig. 12 et 13) m'avoient paru fort gênant dans la pratique, et capable de causer de la douleur; je doutais d'ailleurs de pouvoir par leur moyen maîtriser la langue comme je le voudrais; j'en imaginai donc un nouveau que représente la fig 15, planche 4. Cet instrument rend, tout à la fois, la langue immobile, il tient la bouche ouverte sans qu'elle puisse se fermer, et au moyen d'une plaque polie, qui fait son corps, il réfléchit catoptriquement les rayons lumineux dans le lieu qu'occupe le polype; il est aussi très-aisé à mettre en place, et pour l'y tenir il ne faut que lier derrière la nuque les rubans qui sont attachés à ses deux extrémités." Observations sur la Cure radicale de plusieurs Polypes de la Matrice, de la Gorge et du Nez, Paris, Delaguet, 1749, pp. 294 et 295.

‡ "Will Man daher in einem Winkel sehen, z. B. einen Theil des Schlundes, oder hinter den hängenden Gaumen in die Nasenhöhlen, so müssen die Strahlen gebrochen werden und erfordern Spiegel für die Licht-Reflectionsleitung." Bozzini's Lichtleiter, eine Erfindung zur Anschauung innere Theile und Krankheiten, Hufeland's Journal der prakt. Heilkunde, vol. xxiv., 1 Stück, p. 116.

§ Windsor (*loc. cit.*) refers—without having read them, however—to the following additional articles on Bozzini's invention, viz.: Salzburg. Med.-Chir. Zeit., 1806, iii. pp. 317, 319; 1807, i. p. 271; Siebold, Lucina, iv. p. 167; Journal der Erfindungen, 3 St. p. 89; this last article being to the effect that the instrument is of no use.

§§ "There is no vestige of uvula remaining, and examination with a small mirror does not show any aperture whatever throughout the whole length of the cicatrix." Practical Observations on Aural Surgery and the Nature and Treatment of Diseases of the Ear. With Illustrations. By William R. Wilde. Philadelphia, 1853, p. 347.

There can be no doubt that to Czermak|||| belongs the undivided merit of having formed rhinoscopy into a method, of having named it, demonstrated and defended its feasibility and usefulness, and the crowning glory of having "enlisted fellow-laborers in its practice and given it a future."

The number of physicians who can be induced to take up any such "innovation" is necessarily always limited; and for some time after the introduction of the laryngoscope this instrument occupied attention almost exclusively. But in the spring of 1860 rhinoscopy received an impetus by the publication, by Czermak, of the first pathological rhinoscopic observation, made February 22 and 25 and March 8, 1860.¶¶

Semeleder, who had enjoyed peculiarly favorable opportunities for mastering the new method, at once followed with a detailed description;*** and Voltolini,††† Türck,‡‡‡ Stoerk,§§§ and others, about the same time, not only discussed it in various German and foreign journals, but attracted general attention by successfully practising it in aural and other diseases. Czermak then transplanted it by his celebrated personal demonstrations to France and England, and, before the first half of the year 1860 had passed away, the demonstrations of Stangenwald||||| and a few others had led also to the employment of the rhinoscope in America.

Since that time the disciples of rhinoscopy have steadily augmented in number, and have gained in ability to make practical use of it: still, the method itself has not progressed to its proper place in professional esteem with the same triumphant "quick-step" as laryngoscopy. Its domain being really less known and more difficult to explore, its advance has necessarily been more slow and apparently less brilliant. Its paramount importance, or, I may say, absolute indispensableness, for the diagnosis and treatment of various affections of the pharyngo-nasal space (comprising certain cases of catarrh, deafness from disease in the region of the orifice of the Eustachian tube, etc.), is even to-day not sufficiently appreciated. It has given ample proof, however, of its practical value, and its published literature comprises many exceedingly interesting cases in point.

Anterior rhinoscopy was at first practised by means of an ordinary ear-speculum; then Markusowski, of Pesth, constructed a bivalve dilator, which I have replaced by Elsberg's nasal speculum. Thudichum, of London, devised a spring speculum; Folsom, of New York, a wire nasal speculum adapted from an eye-speculum; and Degen, of Dresden, and Fraenckel, of Berlin, a double wire speculum, which stretches open both alæ of the nose at the same time.

Œsophagoscopy was originated by Lewin, of Berlin. Others have made endoscopic experiments

§§ Zeitschrift der Gesellschaft der Aerzte zu Wien, No. 26, 1860.

¶¶ Proceedings of the New York Medico-Chirurgical College, June 14, 1860; American Medical Monthly and New York Review, vol. xiv., No. 1, July, 1860, p. 18.

with what they called the gastroscope and electrical illumination in glass tubes, but no practical results had been obtained. The honor of having extended the principle of laryngoscopy to the inspection of the œsophagus, dilated for the purpose by means of forceps, is due entirely to Lewin, who exhibited his instruments and demonstrated their application before the Medical Society of Berlin early in 1860. He brought into view the mucous membrane of the œsophagus for four inches down.*

Voltoini, of Breslau, took up the subject and experimented on himself, but was forced to desist temporarily because the practice became too irritating to his throat.†

In the winter of 1862, Semeleder performed œsophagoscopy both on himself and on a patient, and in the latter succeeded in inspecting the lowest edge of the cricoid cartilage,—i.e., more than an inch down into the œsophagus.‡ Soon after, I employed the method in several cases with an improved forceps, and obtained views of the upper portion of the œsophagus.§

Bevan, of London, in 1868, described and figured an œsophagoscope consisting of a tube about four inches long and three-fourths of an inch in diameter, and having a couple of screws and attachment which allow of its easy insertion and adjustment to any angle; to be introduced into the œsophagus and to be united with a tube carrying a mirror which is held in the mouth.||

In 1868, Waldenburg, of Berlin, published the account of a new œsophagoscope, which essentially consisted of two cylindrical tubes sliding in each other, attached movably to a handle, these tubes to be introduced into the œsophagus to take the place of the forceps for keeping the œsophagus open; the mirror and other accessories being the same as for laryngoscopy.¶ More recently, Waldenburg has modified the apparatus by having three rods, somewhat like a wire uterine speculum, to allow of the inspection of the lateral walls of the upper portion of the œsophagus.**

Tracheoscopy down to the bifurcation of the trachea was first accomplished by Elfinger, of Vienna, in Czermak's throat, in April, 1858,†† after which time Czermak himself,‡‡ Semeleder,§§ Lewin,||| Türk,¶¶ and others, confirmed its truth,

and Türk was the first to see distinctly the right bronchus.***

Pertracheal laryngoscopy as well as pertracheal tracheoscopy was devised by Neudörfer, of Vienna,††† but, though he practised it considerably on the dead subject, Czermak was the first to perform it on the living.†††

ORIGINAL COMMUNICATIONS.

CASE OF OPIUM-POISONING—USE OF ATROPIA.

BY H. S. SCHELL, M.D.

AT 7.30 P.M., November 8, 1873, I was called to see L. M., a young woman, who at six o'clock the same evening had taken one and a half fluid-ounces of laudanum for the purpose of destroying her life. I found her unconscious, her extremities cold, muscles relaxed; pulse 60, and full, but not strong; respiration snoring; face of a dusky hue; irides immobile, pupils about $\frac{1}{32}$ inch in diameter, and corneæ insensible.

I had brought with me a couple of yards of india-rubber tubing of small diameter, and a syringe, and, after passing one end of the tube into the stomach, and starting the fluid in motion through it by the syringe, I allowed the other end to fall into a basin by the bedside and thus act as a siphon. In this way a couple of ounces of brownish fluid, smelling somewhat of laudanum, were discharged, when the flow ceased, and could not be again started. While preparing to inject some warm water to wash out the stomach, the tube was accidentally drawn out of the œsophagus, and I was unable to re-introduce it. She had taken no food during the day, and the brownish fluid was evidently mostly beer, of which she had drunk a glass a short time before taking the laudanum. I thought it better, however, to give her an emetic of mustard and salt, to get rid of whatever laudanum might remain; but it was with the greatest difficulty she was sufficiently aroused to be induced to swallow it. I gave her at the same time thirty drops of the tincture of belladonna, and repeated the latter every fifteen minutes until after ten o'clock. The emetic, not acting, was repeated in twenty minutes, and in twenty minutes thereafter was followed by a scruple of sulphate of zinc, and the fauces were tickled with a feather; all without result.

At 9.30 the pulse was somewhat more frequent, but weaker; the condition of the respiration and temperature of the surface remained about the same; and I now noticed for the first time that the optic axes were considerably divergent, the eyeballs being also rolled somewhat upward.

At 10.15, after rousing her to give her a dose of tincture of belladonna, there was an almost convulsive struggle of resistance, attended by violent excitement, and followed by sudden and complete col-

lapse. There was an entire cessation of respiration, the pulse was barely perceptible, the face pale, lips livid, pupils unchanged, and eyes rolled up and outward to the extreme limits of their orbits.

As shaking, slapping, the cold douche, etc., failed to re-excite the act of breathing, I commenced artificial respiration by Marshall Hall's method; and, after keeping it up for ten minutes without improvement, I instructed an assistant how to continue it, and returned to my office for my hypodermic syringe, at the same time sending for a solution of the sulphate of atropia, gr. j ad f3j. On my return, ten minutes afterwards, I found her in the same condition as when I left; not an inspiration being drawn except by the artificial method, and only the feeble fluttering of the heart to show that she was still living.

I at once, however, injected $\frac{1}{4}$ grain of atropia under the skin of the arm, and in a short time had the satisfaction of seeing a natural act of inspiration, and of finding a decided pulse again under my fingers, beating at the rate of 108 in the minute. The pupils soon dilated to $\frac{1}{16}$ inch, and she vomited five or six ounces of fluid. Artificial respiration was of course discontinued, but in a short time the pulse fell again to 90, alarming symptoms reappeared, and twenty minutes after the first injection of atropia I repeated it. The pulse soon rose again. There was copious emesis, but no odor of opium about the ejected fluid. She asked for water, which was given freely, and in the half-unconscious intervals of vomiting she kept up a pretty general scratching of the surface of the body, and rubbing of the nose, showing that she was beginning to be annoyed by the action of the opium upon the skin.

In a little while, however, there was a diminution of the pulse-rate, return of coma, etc., and in half an hour from the last injection I repeated the atropia. The effect now seemed to be more permanent; the pulse rose to 110 and became stronger, the pupils dilated to a little over $\frac{1}{8}$ inch in diameter, and remained so, responding, however, to the action of light. She complained of seeing objects double, and was very tremulous.

When I left her, after 1 A.M., she was dozing quietly, could be easily aroused, her respiration was full, skin warm, pulse 100 and moderately strong, and she had still some divergence of the optic axes.

When I saw her the next morning at 10 o'clock she was sitting by the stove, apparently quite well: the derangement of vision had disappeared, but the thickly-coated tongue and occasional nausea were evidences of considerable derangement of the stomach.

I learned that she had had abundant diuresis during the night; but, owing to accidental circumstances, I was unable to procure a specimen of the urine for examination.

The principal point of interest in connection with this case is the striking manner in which it illustrates the stimulant effect of atropia in moderate doses upon the par vagum.

As to its action upon the gastric branches, it will be remembered that the stomach first responded to

the action of the emetics about two hours after they were taken, and in a few minutes after the first hypodermic injection, and freely after the second one.

Tincture of belladonna had been previously given by the mouth, and about f3ss had been used from the bottle containing it; but, in consequence of the difficulties attending the administration, it is probable that not more than f3ijj were actually swallowed. Owing, however, to the lethargic condition of the stomach, produced by the opium, I imagine that but little of the three fluidrachms was absorbed, and that the most of it was afterwards vomited.

In the case of a man who had taken thirty grains of opium and ten or twelve ounces of whisky,—reported by Dr. McGee,*—the use of various emetics for a couple of hours produced no result; but, after the subcutaneous injection of $\frac{1}{4}$ grain of atropia, free vomiting took place immediately.

In Dr. Walker's case,† a girl fifteen years old had taken six or eight grains of opium, and emetics were used ineffectually until after the hypodermic injection of $1\frac{1}{2}$ grains ext. belladonna.

In Dr. Todd's case,‡ of a man of intemperate habits, who had taken tr. opii f3x, emetics failed to excite vomiting. Atropia was administered subcutaneously at 10.30 P.M., but there was no emesis until after he had been violently rolled about the bed at 3 A.M. In this instance the stomach was probably unusually callous to impressions, in consequence of the habits of the individual.

The action of the remedy upon the cardiac branches of the pneumogastric is seen in the manner in which the pulse rose and strengthened after each use of the hypodermic syringe.

As to the lungs, it has been seen that the use of artificial respiration continued for twenty-five or thirty minutes produced in that time no action of the respiratory muscles, but that the breathing became regular and natural soon after the use of atropia.

I should conclude, therefore, that when the patient is in a comatose condition when first seen, it would be better to administer $\frac{1}{60}$ to $\frac{1}{30}$ grain of atropia subcutaneously at once, and give an emetic as quickly as possible thereafter; and it seems probable that the action of the emetic may be aided by rolling the patient. If, on the contrary, the sulphate of zinc or mustard is allowed to remain in the stomach for an hour or two, it sets up a degree of irritation, or even inflammation, which requires special treatment for its relief and often lasts for several days.

It would seem, too, that there is no advantage in pushing the atropia until the pupils are widely dilated, but that it is sufficient to give enough to stimulate the nervous centres whence the pneumogastric springs to the degree of action necessary to keep the heart and lungs in motion until the system can rid itself of the poison.

A peculiar feature of this case was the divergence of the optic axes,—a symptom which I do not

remember to have seen noticed elsewhere, but which was probably the cause of the diplopia mentioned in the cases recorded by Dr. Johnson* and Dr. Wood,† as it evidently was in this instance. It is possible that there may have been sufficient tincture of belladonna absorbed by the stomach to act upon the nervous centres in the floor of the fourth ventricle, whence the abducens and vagus take their deep origin, and that all the other muscles of the eye, being temporarily paralyzed by the opium, were powerless to resist the external rectus.

1004 VINE STREET, PHILADELPHIA.

AN ABSCESS IN THE PLACENTA.

BY GERALD D. O'FARRELL, M.D.

A SHORT time ago I was called to see Mrs. R., aged 20, primipara. She informed me that she was in labor, and, as far as she could judge, about her full time. Looking at the woman as she lay in bed, I feared that her fond anticipations were not only destined to be disappointed, but that she was far advanced with some malignant disease. A per vaginam examination, however, showed that she was correct. The abdomen was perfectly flat; the face, neck, and breast, as far as visible, were of that green hue seen in well-marked cases of cancer; her eyes were brilliant; emaciation was extreme, and she complained that her hands and feet were burning.

On inquiring into the history of the case, I learned that, when about six months gone, a boy about fourteen years of age playfully struck her a severe blow on the abdomen. From that time she ceased to grow larger, and the movements of the child ceased also.

On making an examination, I found the os uteri sufficiently dilated to admit two fingers, the edges thin, hot, and wiry. Introducing the fingers into the womb, I could feel the bones of the skull denuded of the scalp, and on withdrawing my hand it was covered with a thin, dark-colored, and exceedingly offensive discharge. After several hours I succeeded in dilating the womb sufficiently to allow the head to pass, but was obliged to make a cone of my hand so as to shield the soft parts from injury. The placenta was delivered shortly after. It was hard, dark, granular, and very heavy, and in the body of it I found an abscess containing about twelve fluidounces of fetid pus. The womb did not seem inclined to contract, nor was there much disposition to hemorrhage. I washed out the vagina with a solution of chlorate of potassa in tepid flaxseed mucilage, and put the patient at once on the free use of liq. ferri iod. and quinia. She made a rapid and perfect recovery, and since enjoys excellent health.

PARACENTESIS IN PERICARDIAL EFFUSION.—Mr. Thomas Barlow reports the case of a child, six years of age, who was brought to University College Hospital with an enlarged abdomen, slight œdema below the eyes, cough, dyspnoea, and emaciation.

There was some bulging in the cardiac region; the apex-beat was absent; the cardiac dulness ex-

tended three-quarters of an inch to the right of the sternum, and a double grating friction-sound was heard from the junction of the xiphoid to the junction of the third costal cartilages. There was also slight œdema of the abdominal walls. A week later, the cardiac dulness reached to within a finger's breadth of the right nipple, and there was fluid in the peritoneal cavity. During two months there was but little change in the physical signs; some increase in the ascites, dyspnoea, and emaciation; the jugulars became distended. There being no reason to expect that anything would cause the absorption of the fluid, paracentesis of the pericardium was determined upon. The skin was punctured by the smallest aspirator trocar one inch below and three-quarters of an inch inside the left nipple. The trocar was pushed upward and outward and entered the pericardium above the fourth rib; three and three-fourths ounces of tinted, brownish, highly albuminous fluid were withdrawn. The pulse was unaffected, and there were no signs of collapse. The patient's condition was much improved for two or three days, but in a week it became necessary to repeat the operation. The trocar was introduced on this occasion at the upper border of the fifth rib, and six ounces of fluid were removed. His symptoms were again relieved for a short time, but in two days the cardiac dulness was as great as before. The abdomen became enormously distended, so that paracentesis abdominis was rendered necessary, and was once repeated. The general œdema increased immensely, and the boy died seven months after the commencement of his illness.

At a post-mortem examination there were found extensive tubercular peritonitis, a deposit of tubercle in the right lung, and a partly adherent, partly nutmeg liver. The visceral and parietal pericardium was greatly thickened, but the two surfaces were not at all united, the heart hanging free in its thickened envelope. *The Practitioner*, October, 1873.

RUPTURE OF THE HEART (*British Medical Journal*, October 18, 1873).—Mr. T. M. Wills reports the case of a man, 45 years of age, who was knocked down by a cart and was brought to the hospital in a state of collapse. A contused wound, about three inches in diameter, was found on his chest a little to the left of the sternum, and corresponding to the fifth rib, which was fractured. The pulse- and apex-beats were imperceptible, the surface cold and clammy, lips and hands blanched, respiration troubled and heaving, and there was slight hæmoptysis. In spite of internal and external stimulation, he grew worse, and died in eight hours after the injury. At the post-mortem examination the pericardium was found distended with clotted blood, and a careful examination disclosed at the apex of the left auricular appendix a small laceration, partly filled with a clot, which freely admitted the introduction of a blow-pipe to the cavity of the auricle. The walls of the auricular appendix seemed unusually thin, and there was a large deposit of fat on the walls of the heart, which in other respects was normal. The pericardium was not torn by the rib, and the point of injury was far behind the seat of fracture, so that the rupture must have been caused by the violence of the contusion. The fact of the laceration being remote from the main current of blood, the force of which was diminished by the orifice of the auricular appendix, and also by the shock, explains the survival of the man for so long a period after this accident.

DETECTION OF WATER IN ETHEREAL OILS.—Oils distilled with water from plants contain water, although they may appear perfectly clear. On mixing such oils with an excess of so-called benzine, a cloudy effect is produced by the precipitated drops of water.—*American Chemist*.

PHILADELPHIA
MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 29, 1873.

EDITORIAL.

ATROPIA IN OPIUM-POISONING.

IT is certainly, under most circumstances, an exhibition of bad taste for an editor to laud or to criticise papers appearing in the columns of his own journal. With the permission, however, of Dr. Schell, we propose to offer some remarks upon the subject concerning which his article in this week's issue treats, because it is one of considerable practical importance, and because his case seems to us to fulfil very beautifully the theory first propounded—so far as we know—in the *American Journal of the Medical Sciences* for January, 1872, in regard to the therapeutic action of atropia in opium-poisoning. As most of our readers no doubt know, that theory is that the great value of atropia in opium-poisoning is as a respiratory stimulant,—that just as when, in a case of opium-poisoning, the circulation fails, alcohol in some form is indicated as a cardiac and arterial stimulant, so in similar cases when death is threatened through disturbance of the respiration, atropia should be given.

The first question that naturally arises at this point is, What proof is there that atropia is really a respiratory stimulant? The proof rests partly upon clinical, partly upon experimental, evidence. It is an undeniable fact that in full doses, both in man and animals, belladonna and its alkaloid alike increase the frequency of the respiration; and it has been abundantly proven by experiment that this is by a direct action upon the medulla, since it occurs in animals whose pneumogastriacs have been

previously cut (Bezold und Bloebaum, *Untersuchungen aus dem Laboratorium zu Würzburg*, erster Theil, s. 59). The action of therapeutic and of toxic doses of atropia is somewhat different, since, apparently, the former do and the latter do not paralyze the pneumonic vagi. At least it has been found that whilst after a full dose of the drug the usual results follow section of the par vagum, after a toxic amount the respiratory rhythm is unaltered by the procedure. Perhaps, however, our deduction is too great for the facts in this case.

Death from atropia is very often owing to asphyxia: possibly this is in a measure due to the nerve-centres being overpowered by the stimulus; but another factor certainly enters into the problem, for it has been proven that, like woorari, atropia paralyzes the motor-nerve trunks. Be these things as they may, one evident deduction can be drawn from all the facts,—namely, that in full non-lethal doses atropia is a respiratory stimulant.

It is scarcely necessary to point out that in opium-poisoning the failure of the heart is very generally secondary to failure of respiration.

In the case reported by Dr. Schell, the effect of the drug was very remarkable, in causing a resumption of respiration after it had for twenty minutes failed to occur, notwithstanding the vigorous employment of the usual methods of restoring it.

Whilst we commend the judicious moderation with which the atropia was employed in the present instance, we cannot help believing that often a good deal of firmness is required in these cases not to use it too freely, especially since reliance is generally placed upon the pupils as a guide. They are, however, a very unsafe guide, as is apparent when it is remembered that whilst opium contracts them by influencing the nerve-centres, atropia probably dilates them by acting on the peripheral nerves.

In regard to the guide as to the use of the counter-poison, judgment, we think, should be formed from a bird's-eye view of the whole case, fresh atropia not being given so long as the respiration and other symptoms are undergoing amelioration, but the dose being renewed so soon as any tendency to a relapse is manifested. Thus, if under the influence of atropia in a case the respirations had risen from four to eight per minute, we would not use the counter-poison again until there was manifested a tendency for the respirations to grow less frequent, or unless for a long period there had been no improvement.

Space is of course wanting here to enter into an elaborate discussion of the subject; but it has been proven by the researches of numerous observers

that the sole action of atropia upon the peripheral cardiac par vagum, and with scarcely a doubt upon the whole peripheral par vagum, is that of a paralyzant. The rise in the rapidity of the heart's action in belladonna-poisoning is very largely due to the removal of the inhibitory power. The explanation we would give of the vomiting which occurred after the injections is, therefore, different from that offered by the reporter. It seems to us that the double nature of the profound opium-narcosis has not had sufficient stress laid upon it. We have not rarely seen a child whose lungs were filled up with the exudation of capillary bronchitis offer symptoms exactly similar to those of the advanced stages of opium-poisoning,—the general relaxation, the profound insensibility, the contracted pupils, the slow, distant efforts at breathing, being all present,—and we have seen the same child under the influence of alternate ice-cold and hot douches commence to breathe; and, as the breathing returned, have watched the pupils dilate, the cyanotic hue pass from the face, and the child arouse itself out of its unconsciousness, only to relapse when the breathing was allowed to fall back. We have treated such a case almost as one of opium-poisoning, and, after four, six, or eight hours, have seen assurances of returning life,—assurances ending in recovery, when for hours the child had been unable to swallow, and the case abandoned by the most skilful physicians as hopeless.

What is the cause of the narcosis in these cases? Evidently, carbonic acid gradually accumulated in the blood through the failing respiration. Precisely the same thing happens in opium-poisoning,—failing respiration, accumulation of the gas in the blood, a double narcosis, due perhaps even to a greater degree to the carbonic acid than to opium. Carbonic acid narcosis suspends reflex actions; we have experimentally corroborated this well-known fact: hence the emetic will not act in a case like that of Dr. Schell's. When, however, the respiration begins to return, when a portion of the carbonic acid has been removed, the emetic is able, as it were, to pierce through the thinned stratum of narcotics and to reach the living nerve below.

IF the telegraphic dispatches be true, a most extraordinary instance of professional pride has just been given in Boston. Recently we chronicled the self-immolation of Obermeier, a young Berlin physician, upon the altar of science; but this time it is simply personal and professional pride that has brought about the tragic result, unless—as seems to us probable—there were some deeper, hidden

springs of action. The story is that in the Boston City Hospital a young female nurse, named Pfyffer, on Tuesday, November 18, took opium with suicidal intent. Dr. Arthur L. Foster, the house physician, was called to her in the night, and mistook her symptoms for hysteria, prescribed, and returned to his bed. The next morning, on finding that his patient was dead of opium-poisoning, he went to the bath-room, and, locking the door, opened a femoral artery.

CORRESPONDENCE.

LONDON LETTER.

[From Our Own Correspondent.]

Mr. Erichsen's Address at University College—Hospitalism—Mr. Callender's Papers on the Subject—A Doctors' War—Death of Dr. Murray—Breach of Professional Rules—Death of Sir Henry Holland.

LONDON, November 5, 1873.

AMONG the most important of the Introductory Addresses at the Medical Schools in London, this season, was that of Mr. Erichsen, the well-known author of "The Principles of Surgery." It was delivered at University College under peculiar circumstances. The physician to whose turn it fell (for it is a matter of rotation) to deliver the address was Dr. Roberts, a young assistant-physician of great promise, and also the venturous author of a New Handbook of Medicine just issued from the press and not yet reviewed. Dr. Roberts, however, fell into bad health; and Mr. Erichsen, who has just recovered from a serious illness, due, it was thought, to "chronic blood-poisoning," had probably most of the materials for an oration at hand,—those, namely, which he had prepared for the Address in Surgery which he was early in the year appointed to give for the British Medical Association. Mr. Erichsen's address was, accordingly, out of the class of ordinary inaugural addresses. It bore the marks of much thought and preparation and treated seriously an important subject, and was in truth a sort of review of the progress of surgery and a survey of its prospects.

It has produced a very serious impression, owing to the way in which it dealt with the subject, and is likely to be the signal for reopening vigorously the great question,—deeply interesting to surgeons and to the world at large,—How far is the influence of *hospitals* injurious to patients undergoing operation in them? What is the rightful meaning of the word *hospitalism*, to which the late Sir James Y. Simpson attached a sinister significance? How far is the alleged baneful influence of hospitals an essential condition of residence in hospitals, and by what precautions can it be diminished?

Mr. Erichsen's statements were slashing, and they have not passed uncontradicted. I believe that your continent is capable of contributing perhaps more important evidence in the discussion of the question than even our European hospitals and private records can furnish, and I am sure that such contribution will be

received with great satisfaction. It is a question equally momentous on both sides of the Atlantic; and therefore I call the particular attention of American surgeons to it. The creed of Mr. Erichsen is stated so broadly and clearly that I shall do best to quote the passage in which he re-states and endorses Simpson's figures:

"Without going into details, which would here be alike unnecessary and tedious, it may be stated broadly that, having collected a large and nearly equal mass of statistical returns of consecutive operations performed in large and in small hospitals, in country, mining, and private practice, he found that of 2089 cases of amputations in large hospitals in this country, 855, or 1 in 2.4, had died; whilst of 2068 in country and private practice the deaths were only 226, or at the rate of 1 in 9.2.

"It is quite possible that Simpson's figures may not be absolutely, but only approximately, correct, and that certain sources of fallacy have introduced themselves into his tables. But, making all reasonable allowance for every possible source of error, the difference is so great between the operation of amputation in and out of hospital that the material result cannot be affected,—viz., that a mortality of 1 in 2.4, or, in other words, of more than 40 per cent., is not a necessary result of amputations; that it is greatly the result of the circumstances in which the patient is placed after the operation; and that it may be materially reduced,—according to Simpson, by nearly three-fourths,—so as to amount to less than 12 per cent., by an alteration of these circumstances; and that the mortality so dependent on circumstances which admit of alteration, of modification, and probably of rectification, is certainly equal to that which exceeds 1 in 9, or 12 per cent.

"But, when we come to analyze these results more closely, some startling facts are elicited. Thus, amputation through the forearm cannot surgically be considered a very serious operation. It is not likely to prove fatal by any conditions dependent on or inherent in it,—as, for instance, by shock or hemorrhage,—but can only become fatal by the intrusion of other and adventitious circumstances dependent on causes existing outside the operation itself. Well, what is the result? That of 377 cases occurring in private and country practice only 2 died, whilst of 244 in hospitals no less than 40 died, being 1 in 188 against 1 in 6.

"Surely here is a condition of things most unsatisfactory in itself, and not very creditable to modern surgery, and one in which we may hope that the further cultivation of the science may do much to aid the progress of the art of surgery."

Accepting thus sincerely Simpson's figures as unimpeachable, it is not surprising that Mr. Erichsen should ask, "Must hospital surgeons ever remain content in losing from one-third to one-half of all their amputations, and nine-tenths of some?" or that, addressing the students, he should say to them, "Here, then, is a vast and most fertile field, to which you who are commencing your studies may direct your attention with the greatest advantage, and which you who after this session will go forth into the world to practise may cul-

tivate with a double advantage, to humanity and to yourselves."

It happens, however, that some others than students just commencing their studies have been directing their attention to this most fertile field, and have endeavored to ascertain what the utmost care and a judicious and minute attention to the recognized rules of surgery can do to reduce hospital mortality after operations to a par with anything that can be claimed for domiciliary surgery. Prominent among these has been Mr. George Callender, F.R.S., one of the surgeons to St. Bartholomew's Hospital, who has succeeded to the charge of Sir James Paget's wards in that ancient and noble institution. Mr. Callender read a paper making known his results at the last meeting of the British Medical Association, London, August, 1873. In this paper he gave a table showing the results of the treatment of compound fractures and of amputations during the last four and a half years, the whole period of his surgeoncy. The table is a very remarkable one: it reads thus:

	TOTALS.	DIED.	RECOVERED.	FATAL CASES.
Operations (excluding those for hernia)	199	6	193	
Compound fractures	28	0	28	1. Ovariectomy.
Amputation at the thigh	14	0	14	2. Ovariectomy.
" " leg	14	0	14	3. Nephrotomy.
" " arm	2	0	2	4. Lithotomy.
" " forearm	3	0	3	5. Syphilitic laryngitis.
	33	0	33	6. Cystic tumor.

Thus it will be seen that there has been in these wards during four and a half years a death-rate after all operations (excluding hernia) of but three per cent., and that of the thirty-three cases of amputation, including fourteen of the thigh and fourteen of the leg, all have recovered. The twenty-eight cases of compound fracture have likewise all recovered; and this explains the absence of cases of primary amputation in the list. It may be doubted whether the results of any surgeon in private practice ever exceeded this; and hence some lectures which Mr. Callender is now publishing in the journal of the Association (*British Medical Journal*), explaining all the details of his treatment, are attracting great attention. They, however, contain little that is new in principle,—indeed, they do not profess to do so,—but they are highly interesting, as showing how important is the attention to small things, and how greatly results are influenced by the most conscientious devotion to details. Rest, isolation, scrupulous cleanliness, antiseptic applications (without the exclusion of air), and a minute and intelligent supervision of everything which can avoid septic poisoning of the wound and improve the patient's condition,—these are the secrets of Mr. Callender's success. I should say that Mr. Callender is a man remarkable for scrupulous exactness in word and act; he is as conscientious in what he says as in what he does; and, besides the fact that all his cases are controlled by public record in the books and papers of the hospital, there is no one here who hesitates to accord the most implicit reliance to his statements, as being sure to be entirely free from every conscious exaggeration, and certainly from every kind of statistical

juggle. The whole question of hospital mortality is likely, therefore, now to be transferred from the region of paper statistics, in which it has rested for a long time, to its proper field, that of actual clinical experiment in the wards of great hospitals. I shall have again to return to this subject (which I do not doubt that you will agree with me in thinking of deep interest); for Professor Erichsen and Dr. Lauchlan Aitken (who assisted the late Sir James Y. Simpson in preparing his statistics) are likely to take the field again shortly on his side of the question, while the series of lectures which Mr. Callender has now commenced will give a minute review of his methods and results, and of those of his colleague at the hospital, Mr. Morrant Baker, which have been hardly less interesting and successful.

The Societies have recommenced, but as yet without any promise of papers of more than ordinary interest. The next meeting of the Clinical Society will, however, produce two interesting papers by Sir William Gull, which may be worth discussion. The most ordinary topics of interest are the preparations for the Ashantee expedition, which is to be a doctors' and an engineers' war chiefly. A few years ago "a doctors' war" would have been a phrase not easily understood by the million. Now, however, it is beginning to be pretty well understood that in a tropical campaign "the wise physician skilled our wounds to heal" (and to prevent) is sometimes "more than armies to the public weal."

A very general and most unusually earnest and outspoken feeling of grief has been caused by the almost sudden death of Dr. John Murray, who, though under thirty years of age, was well known as sub-editor of a medical paper, and was already physician to two leading hospitals. He was carried off suddenly by an attack of erysipelatous inflammation of the fauces, followed by rapid œdema of the larynx. His remains were removed to Aberdeen, his place of birth: they were met at the railway-station by upwards of four hundred of the best-known London practitioners, and a funeral service was there conducted of singular solemnity and strangely sad impressiveness. A tablet and bust will be erected to his memory. Some excellent Latin and Greek lines have been published *in memoriam*. As classical tributes of the kind to the memory of physicians are becoming unfortunately rare, and as both are from the pens of London medical men, I will quote the Greek, which is much admired for its point and classic neatness of diction:

Τί τοῦτο, Θάνατε ; Μὴν ἀφάρπασαι δοκεῖς
Ἰατρὸν ὃδ' ἀνέβου, ὡς τέχνης φθονὸν ;
Οὐκ ἔστι· καὶ γὰρ ἐγγεγραμμένος φρεσὶν
Φίλων, πενήτων, πάντος ἱατρῶν γένους,
Ἄπῳ παρέστι, καὶ σὲ νικήσει θανόν.

"And didst thou think, O death, to gain
A victory by having slain
Him so young, so full of skill?
Ah, no! for he is living still.
He lives enshrined in many a heart,
Friends, brothers, debtors to his art.
Thus, though absent, present, he
In dying, death, shall conquer thee."

From a physician much honored I must pass to one who has incurred professional censure. A well-known physician of St. Thomas's Hospital, greatly to the surprise of his professional brethren, lately undertook to edit a column, entitled "Our Medical Column," in a weekly paper called "The English Mechanic." This is entirely contrary to obvious rules of professional ethics. He defended himself vigorously and defiantly when called to account by the medical papers, and alleged—no doubt truly—purely philanthropical motives. But, whatever the motive, the course was obviously wrong; and, after a very brief struggle, he has succumbed, not without some loss of consideration among his professional brethren here, who do not easily pardon such a breach of professional rule. The struggle was so brief that the College of Physicians and the staff of his hospital have been relieved from the necessity of interfering.

The death is announced to-day of Sir Henry Holland, a physician who has occupied the highest social position for many years, and who was of great literary and scientific distinction, but who was not very well known personally in medical circles, from which he held himself unduly aloof. He died at the age of eighty-five, quietly in his bed, after a very few hours of languor, having recently returned from one of those long vacation-rambles far afield (this time to the fair at Nijni Novgorod in Russia) in which he had annually indulged throughout his long and active life. He was a frequent visitor to America, and the friend of many distinguished American citizens,—among others, the personal friend of six Presidents of the United States. His first wife was a daughter of the late Canon Sydney Smith.

PHILADELPHIA, Nov. 20, 1873.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES.

DEAR SIR:—I send the following clipping from the *Public Ledger*. What chance have the hospital doctors against an accoucheur with a baby of seventeen and three-quarters pounds weight?

"A BOUNCING BOY BABY.—Mr. John Brooks, 1728 Warnock Street, has been furnished by the attending physician, Dr. Prall, with the following particulars concerning his new-born son, Henry C. Brooks, born on Tuesday last, November 18:

Weight	17½ pounds.
Length	22½ inches.
Measure around the shoulders	19½ "
Measure around the waist	17½ "
Measure around the chest	17¼ "
Measure around the head	16 "

"Perhaps some of our experienced doctors, or affectionate mothers, may be able to present cases approaching the dimensions of this young gentleman on his birthday: if so, the *Ledger* will help to make an enduring record of the fact."

Yours,

CONTRIBUTOR.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

ANNUAL MEETING, NOVEMBER 11, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

THE Society was called to order at 3.15 P.M.

The minutes of the last semi-annual meeting were read and approved.

A communication from the State Medical Society was presented and read by the Secretary, and was received and accepted.

The President announced that the committee would be appointed at a future time.

The report of the Treasurer was then read by the Treasurer, Dr. W. H. Murray, and was received and adopted.

The report of the committee on publications was then read, and, after a lively debate, was laid on the table.

Drs. Segur, P. A. Fennelly, and O. H. E. Clarke were elected as members of the Society.

After various miscellaneous business, the President delivered an admirable address, and the following were elected officers for the ensuing year:

President—John Swinburne.*Vice-President*—H. W. Steenburgh.*Secretary*—F. C. Curtis.*Treasurer*—W. H. T. Reynolds.

The remainder of the officers continue the same as last year.

The Society then partook of a banquet, with the usual accompaniments of toasts, speeches, etc.

GLEANINGS FROM OUR EXCHANGES.

FALLACIES AND FAILURES IN ANTISEPTIC SURGERY (*British Medical Journal*, October 18, 1873).—Mr. Edward Lund, surgeon to the Manchester Royal Infirmary, and one of the advocates of the antiseptic system, enumerates a few of the erroneous notions which are entertained on this subject. He says:

"1. It is a fallacy, or an erroneous doctrine, in the practice of antisepticity, to think that it is the agent employed, and not the result produced, which must be watched. Carbolic acid is only useful by preventing putrefaction in the excreta of the wound, and to say that it has any special power beyond is a mistake.

"2. It is a fallacy to assume that the success or failure of the system is to be measured alone by the absence or presence of suppuration.

"3. It is a fallacy to look upon the secretion and expulsion of pus as so much broken-down tissue, produced by the removal of previous induration, the reduction of swelling, and the clearance of the general system of some peccant matters.

"4. It is a fallacy to regard the admission of air to wounded portions of the body as a matter of light importance, unless the air be filtered and disinfected of its septic particles.

"5. It is a fallacy to ignore the possible contagion of septic matters from one wound to another, from one person to another, from tainted instruments and soiled dressings, and thus to neglect the most scrupulous cleanliness in the treatment of wounds, by quick removal, from within their range, of the minutest portions of the products of putrefaction.

"6. It is as fallacious as it is inconsistent to attribute on the one hand to atmospheric causes the presence of pyæmia, septicæmia, erysipelas, and the like, and yet to take no precautionary measures which can be proved to be efficient to neutralize these ill effects in the treatment of wounds."

In regard to the sources or causes of failure which may vitiate the ultimate results of any operation conducted on antiseptic principles, there may be mentioned:

"1. Non-attention to the needful preparations before the operation is commenced, in reference to the part to be operated upon, the instruments to be used, and the assistants who are to take part in it. This applies as much to the treatment of abscesses as of wounds properly so called, for the entrance to the abscess must be most carefully guarded at the time of incision.

"2. Defective arrangements during the progress of the operation, from its commencement to its entire completion.

"3. Faulty adjustment of the dressings after the operation is finished, such as allowing them to pucker up and thereby leave channels or cavities so capacious that more air collects in them than the vapor generated from the resin cloth or gauze can disinfest.

"4. Injurious delay in redressing the wound for the first time after the operation, so that the discharges, having exuded through the layers of whatever antiseptic material may be employed, reach the air, become putrid, and have their septic influence carried backward to the wound.

"5. Carelessness in the special method of removing the old dressings and applying new ones, even where the atmosphere is assumed to be rendered innocuous by antiseptic vapor.

"6. Needless alarm at certain complications which may arise, and, being regarded as harbingers of evil, cause the neglect or total abandonment of the system. The most common of these complications is the sudden appearance of redness in the skin near the wound, seeming to forebode the advent of erysipelas. It rarely goes beyond the condition of severe erythema."

GUNSHOT WOUND OF THE HEAD (*St. Louis Medical and Surgical Journal*, November, 1873).—Dr. T. F. Prewitt reports the case of a man, æt. 32, who, while endeavoring to shoot himself, inflicted a wound a little to the left of the median line of the forehead and about an inch and a half above the supraorbital ridge. The bullet entered the cranium, and the bony circumference of its track through the skull could be traced with a probe for several inches. The man suffered somewhat from irritability of the stomach, nausea, and vomiting, but this condition was relieved by chloral and morphia. He was kept quiet, and in five weeks was discharged from the hospital greatly improved. About a year afterwards he came under observation again, complaining of great headache, involuntary discharges of urine, and general malaise. He sank gradually, became semi-comatose, and finally died of asthenia.

On the post-mortem examination the bullet was found encysted and lying near the anterior border of the left lobe of the cerebrum, upon the under surface of which was a large sac filled with pus. There were evidences of inflammation of the brain and dura mater in the neighborhood of the ball.

TRAUMATIC TETANUS SUCCESSFULLY TREATED WITH CALABAR BEAN (*Chicago Medical Journal*, November, 1873).—Dr. J. A. Duncan resorted to calabar bean in a severe case of traumatic tetanus, after enormous doses of opium, chloral, ether, belladonna, and bromide of potassium had been given without benefit. A tincture of the bean was used containing one grain of the powdered drug to four minims of the menstruum. Fourteen

drops were given at once, and subsequently nine drops every two hours. In four hours a troublesome spasmodic contraction of the neck of the bladder was overcome, a quart of urine was passed voluntarily, and the pulse fell from 104 to 80. His general condition, however, remained about the same. The remedy was continued in large doses (eight drops every three hours) for fifteen days, when, as there was not much change for the better, fifteen drops were given every three hours for the entire day. The following day—the twentieth of the disease—the patient was able to leave his bed, ate with great appetite, and from that time progressed steadily to complete recovery.

TINCTURE OF DIGITALIS AND CHLORAL HYDRATE IN DELIRIUM TREMENS (*Boston Medical and Surgical Journal*, October 16, 1873).—Dr. E. Chenery records the case of a Scotchman, aged 35, who, when first seen, had neither taken food nor slept for nearly a week, during which time he had been on a continuous debauch. His mind was greatly agitated, his muscular system in a state of unrest, and his pulse feeble and frequent. A strong mustard plaster was applied to the pit of his stomach, fifteen grains of chloral were given, and in twenty minutes twenty drops of the tincture of digitalis. These were retained, and in ten minutes thirty grains of chloral were administered, and were followed by three hours of refreshing sleep. A raw egg and some milk were then given, with another portion of digitalis, and in a short time thirty grains more of chloral. This time he passed off into a sleep of many hours, from which he awoke much relieved. Small doses of digitalis were continued for several days, partly to reduce the pulse, but principally for the sake of the eliminative action on the kidneys.

POISONING BY RED PRECIPITATE (*Irish Hospital Gazette*, October 15, 1873).—Mr. Russell reports the case of a girl, æt. 15, who by mistake took half an ounce of red precipitate. She was admitted to the hospital a few minutes afterwards, having no urgent symptoms whatever. An emetic of sulphate of zinc was administered, and abundance of milk was ordered as diet. The following day her lips, gums, and mouth were very sore, swollen, and reddened, she had a distinct mercurial fœtor from her breath, with headache, and pain in the epigastrium. She was ordered thirty minims of Battley's sedative liquor, an alum gargle for her mouth, and poultices to the epigastrium. She began to improve immediately, her bowels were gently moved by a dose of castor oil, and she had no further trouble from the effects of the drug, except that in about a week she lost two front teeth, and her mouth remained slightly sore for a few days longer.

INFANTICIDE (*The Lancet*, October 11, 1873).—Dr. W. Handsel Griffiths calls attention to the fact that a sharp instrument, such as a needle or bodkin, can be thrust up under the upper eyelid of an infant, made to pierce the orbital plate of the frontal bone, enter the brain, and cause death with no other symptom than a convulsion, and not only leaving no external mark whatever, but causing neither a fracture of the bone nor the escape of a single drop of blood. In experiments on animals Dr. Griffiths has found the utmost difficulty in detecting the wound on making a post-mortem examination; and he suggests that in cases of sudden death of infants from "convulsions" it is the duty of the medical man to make an autopsy as soon as possible, and investigate minutely the state of the orbital walls.

WOUND OF THE ABDOMEN (*British Medical Journal*, October 11, 1873).—Mr. W. Nettle reports the case of a boy, aged 16, who while climbing over a gate slipped and fell on one of the iron spikes with which its top was covered. He at first felt sick and faint, but soon

recovered, and walked home, and did not discover, until undressing for the night, that he was wounded. There was in the left inguinal region an opening about an inch in length, through which protruded a tightly-constricted piece of omentum. This was replaced, the wound closed by sutures, and the boy sent to bed, which he left in a fortnight perfectly well.

EFFECTS OF PRESSURE ON THE FŒTAL HEAD (*British Medical Journal*, October 18, 1873).—Dr. J. Matthews Duncan reports a case in which a persistent digital impression was produced on the parietal bone of a fœtus during birth by the finger of the accoucheur, who was endeavoring to effect artificial rotation. The result was slight, short, but frequently repeated, epileptiform seizures, which lasted some time after the digital impression had disappeared, and which were finally replaced by choreic movements.

THE MEDICAL VALUE OF ARTERIAL PRESSURE.—In experimenting with the sphygmograph, some years ago, Mr. Edward De Morgan made the following deductions, which, with their practical application, he now makes public. When pressure is applied to both axillary and femoral arteries, about half the blood in the systemic or greater circulation is withheld. The remainder returns to fill the left ventricle of the heart, which either contracts upon half its normal amount of blood or delays its systole until sufficient blood has returned from the unobstructed vessels to distend it to its normal contracting volume. In the latter event the pulse would be diminished in frequency and increased in fullness: the sphygmograph, however, shows that this is not the case when the arteries are compressed. Hence it follows that the left ventricle contracts upon half its normal quantity of blood, that the right ventricle does likewise, and that, the area of the pulmonary or lesser circulation being undiminished, the pulmonary artery contains but half its proper amount of blood, which must therefore speed through it less rapidly and with diminished pressure upon its walls.

Mr. De Morgan determined to apply this theory in the hæmoptysis of consumptive cases, in traumatic pulmonary hemorrhage, as a direct *dry cupping* of the lung in inflammatory diseases, and, on the supposition that damming back venous blood from the lungs would diminish the necessity of oxygenation, in spasmodic asthma and cardiac and emphysematous dyspnœa. He briefly records the results of a few cases in which he obtained great success by this plan of treatment. In a patient with a bullet-wound of the left lung, and with great pneumothorax and hæmothorax, axillary pressure gave immediate relief to the dyspnœa. In a young lady with spasmodic asthma the paroxysm was cut short by the application of the thumbs to the axillary arteries; and the same means instantly relieved the suffocative distress of an old gentleman with chronic bronchitis and emphysema. Mr. De Morgan has found that cardiac dyspnœa is not benefited in nearly the same degree as that of pulmonary origin, but that in the latter relief is immediate and unailing.—*The Lancet*, September 20, 1873.

PROFESSOR BETZ'S METHOD OF MAKING SECTIONS OF NERVOUS TISSUE (by Dr. Batty Tuke).—Professor Betz, of Kiew, has lately produced brain-sections which have attracted very considerable attention in Vienna. His specimens are of vast extent. He appears to be able to produce thin sections of an entire hemisphere. We append his method of hardening and cutting as it is stated in the "Correspondenz Blatt der deutschen Gesellschaft für Psychiatrie und gerichtlich Psychologie," January, 1873. The method of hardening which we wish to bring into notice is as follows,—observing that differences exist in the treatment of the spinal cord,

cerebrum, and cerebellum. The spinal cord, after the careful removal of the dura mater, is placed in spirit of from seventy-five to eighty per cent., which is tinged a clear brown color by the addition of iodine. After from one to three days, during which the preparation must stand in a cool temperature, the pia mater and the arachnoid are also removed, the specimen remaining in the spirit, to which a few drops of iodine must be added daily for three days, maintaining an ordinary temperature. It is then transferred to a three per cent. solution of chromate of potass, and back again to the cool temperature. Here it hardens thoroughly, which is known by the fluid becoming turbid, and by the formation of a brown deposit upon the preparation. When this occurs it must be immediately thoroughly washed with water, and immersed in a solution of chromate of potass, from a half to one per cent. strength, in which it will not become too hard or brittle.

Preparations of cerebellum can only be made when it has been taken from a perfectly fresh body. Before immersing it in the iodine spirit, the vessels and membranes must be carefully removed, especially at the vermiform process and the "square lobes;" and cotton wool should be stuffed into the sulci on either side of the process, the rhomboidal groove, and the nates and testes, should they be in the specimen, so as to render the passage of fluid into the deeper parts more easy. The preparations should rest on cotton wool. The iodine spirit should be quickly increased in strength. After from seven to fourteen days the specimen should be placed, provided it does not give to the finger, in a five per cent. solution of chromate of potass.

The *great brain*, after being divided in half through the length of the corpus callosum, is laid in weak iodine spirit. After some hours the separation of the membranes in the fissure of Sylvius, and at the tail of the corpus callosum, should be commenced, so as to allow of the permeation of the spirit. The preparation must stand in a cool place (during summer in an ice-cellar). After from ten to fourteen days it is removed to a four per cent. solution of chromate of potass. When sections are to be taken, it must be washed carefully in water.

The Cutting of Sections.—Betz endeavors to avoid all rubbing of the knife on the surface of the preparation, and sticking of the section on the upper surface of the blade. To this end he has had constructed a knife whose upper surface is convex, the under one concave, the radius of the lower one being somewhat smaller than that of the upper. The blade is from one and a half to twice as long as it is broad, the thickness being one-third of the breadth. For large cross-sections, as for instance through the whole hemisphere, Betz uses a knife whose blade is twenty-one centimetres (eight and a quarter inches) long by ten centimetres (four inches) broad. This form of knife (hatchet?) makes it possible to keep the surface of the preparation and the section constantly wet by means of dropping spirit, so that rubbing on the one and sticking of the other may be avoided.

Details are given of the form of section-machine, which, except of course in size, is constructed on the same principle as the one in use in this country.—*London Journal of Mental Science.*

CHLORAL IN NOCTURNAL INCONTINENCE OF URINE.
—Dr. William Thompson gives the following directions for the employment of chloral in nocturnal incontinence.
1. Only give it at night, the patient having fasted for two hours before going to bed. 2. Give it in full doses and when in bed. 3. Let the patient have as little fluids as possible; beer and spirits to be positively prohibited. 4. Not to be continued longer than a week or ten days: if benefit is not derived within that period, the case is either not one of incontinence depending

on habit solely, or the peculiar idiosyncrasy of the patient prevents the beneficial action of the chloral.—*The Lancet*, September 20, 1873.

MAGNESIA AS A SURGICAL DRESSING.—Dr. Ohlmeyer, of Weissenburg, has found the carbonate of magnesia of value,—

1. In atonic ulcers.
2. In cases where the epidermis was eroded and the subjacent tissues were the seat of pain and were prone to subsequent suppuration.
3. In relieving the pain of inflamed wounds.
4. In cases where it was desirable to stimulate the affected surface, prevent the access of air, and limit the formation of pus. He was led in the first instance to try this remedy from its well-known action in those states of the stomach where there is an excessive formation of acids. These latter, uniting with the base magnesia, are neutralized, and carbonic acid evolved. Accordingly, he believes that in exposed surfaces where the process of healing is prevented by fermentative action, this dressing is indicated. The use of it was attended with satisfactory results. The magnesia unites with the acids which form on the surface; it excludes the oxygen, forms an artificial covering, irritates the granulations, and forms a barrier against external and harmful agents.

In preparing the application he selects a fluid that will not readily oxidize. Oil answers this indication, and the kind he employs is the oil of sweet almonds. Adding to this the carbonate, he makes a tolerably fluid paste of salve. This is then spread upon linen and laid over the wound. It is held in place in the ordinary way.

Dr. Ohlmeyer also adds that he has used the carbonate successfully in facial erysipelas, when it was important to protect other patients from infection. In this latter case he used water as a substitute for oil.—*The Clinic*, from *Allg. Med. Central-Zeit.*, xlvii., 1873.

ADMINISTRATION OF PODOPHYLLIN (*British Medical Journal*, October 18, 1873).—A. E. Barret recommends the following formula when it is necessary to give podophyllin:

R Podophyllin, gr. ivss;
Extracti elaterii, gr. ivss;
Pulv. jalapæ comp., ʒvj.—M.

Half a drachm of this powder in half a pint of warm water acts most effectually, the cholagogue effects of the podophyllin seeming to be assisted by the hydragogue. Its use is not apt to be followed by constipation.

MISCELLANY.

A RECENT writer in *The Belgravia*, in an article on toads, says, "Any book of folk-lore will show how much the medicine of the mediæval period dealt with all kinds of reptiles and other such 'uncanny animals' as hedge-hogs, bats, owls, and other weird and darkness-loving things. Serpents, we know, were sacred to Æsculapius, not on account of their supposed wisdom or subtlety, but by reason of their yearly renovation in a change of skin; and it would seem that all the reptiles of the lizard and frog classes, which inherit some share of the enmity sown in Eden between the seed of the woman and the seed of the serpent, inherit also some part of this affinity between snakes and the practice of medicine. I find that the homœopaths of the present day retain at least one drug obtained from

snakehood,—‘lachesis,’—which is said to be the poison of the lance-headed viper, though it may perhaps be doubted whether their chemists have really supplied their vials from the poison-bag of that interesting reptile. They also use the sepia of the cuttle-fish; and I have often been struck by the appropriateness of sepia as a medical emblem. I observe that doctors, when hard pressed in argument, always escape in a flood of hard words, like the cuttle-fish, protected and concealed by the blinding inky trail it leaves behind it.”—*Littell's Living Age*.

PROSTITUTION IN JAPAN.—Japan has many “soiled doves;” and, among the social reforms of last year, it has freed them from the obligation of their contracts, to which in many cases, according to the last consular report, they “had never been willing parties.” The uncaging, however, has been effected without due regard to consequences, and their escape from the brothel-keepers and subsequent flight through the settlements has converted them into “carrier-pigeons” of a very dangerous breed, distributing disease right and left among natives and foreigners. Thanks to Staff-Surgeon Hill, R.N., in charge of the Lock Hospital at Kanagawa, whose post would have declined into a sinecure from the hasty action of the authorities, street-prostitution has been suppressed, and the majority of the women gradually disbanded and sent to their homes either in the neighborhood of Yokohama or at a distance from it. Under the new system, each woman pays a license-fee of three dollars a month to the local government; but Dr. Hill views with regret the action of the authorities in compelling the women to pay their own Lock Hospital expenses. The consul at Kanagawa is in hopes that a portion at least of the revenue thus derived, which is likely to amount to some 30,000 or 40,000 dollars per annum, may be applied to the relief of the unfortunate class.—*The Canadian Medical Times*.

TO COOK RICE.—The following is an account, taken from an old number of the *Gazette des Hôpitaux*, of the method recommended by the French Academy for cooking rice, during the siege of Paris. Take one cup of rice and one-fourth of a cup of water in a saucepan, cover and place over a good fire; after an hour the water will be evaporated, and the rice cooked tender, but dry, and with the grains distinct,—not in a paste. Sufficient salt should be added in the first place, and care should be taken not to disturb the rice whilst cooking.

By adding a little butter, and allowing the rice to dry a little more over a gentle fire, a more delicate dish is prepared.

Rice cooked in this manner, which is the same as that employed in the East Indies, bears the same relation to the indigestible paste of the New England kitchen as does bread to boiled flour.—*Boston Medical and Surgical Journal*.

PREVENTION OF TORMENTING OF HORSES, ETC., BY FLIES.—M. Lochard, a veterinary surgeon, describes a simple and economical means of preventing the suf-

fering which is induced in horses and other animals by the persecution of flies, and which our provincial readers will probably be induced to try. It consists in painting with a pencil the insides of the ears, or other parts liable to be bitten, with a few drops of empyreumatic juniper oil (*huile de cade*). Insects will not approach the parts so painted, and the cost of the oil is trifling.—*The Clinic; from Journal de Connaissance Méd.*

THE SIX FOLLIES OF SCIENCE.—The six follies of science are said to be the following: the quadrature of the circle; the establishment of perpetual motion; the philosopher's stone; the transmutation of metals; divination, or the discovery of secrets by magic; and, lastly, judicial astrology. It is unwise to say that anything is impossible, until the impossibility is demonstrated. It is not at all improbable that the present century may see that one of these so-called follies is a reality.—*Journal of Applied Sciences*.

THE value of roasted coffee as a disinfectant, or rather deodorizer, is well known to housewives. In the London *Lancet* of October 25, Dr. William Story commends it highly as an application to foul ulcers.

NOTES AND QUERIES.

A CORRESPONDENT suggests that there be a department of Notes and Queries in the *Philadelphia Medical Times*. Although somewhat doubtful as to whether there is any demand for such department, *i.e.*, whether sufficient queries will be presented to make it lively, we are willing to try the experiment. We would like to combine with it a department for original tried formula, because no doubt some queries will be in such direction, and would ask our readers to furnish any they may have.

Correspondent.—What is meant by the expression “hydatids with echinococcus,” used in a recent book notice?

Answer.—The expression is somewhat tautological, as all hydatids contain echinococci or their remains. Perfect echinococci, with the sac and hooklets, are often not to be found; and we suppose the expression meant that they were present.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 18, 1873, TO NOVEMBER 24, 1873, INCLUSIVE.

ABADIE, E. H., SURGEON.—To report by letter to the Commanding General Military Division of the Atlantic, for assignment to duty. S. O. 230, A. G. O., Nov. 18, 1873.

BILL, J. H., SURGEON.—Granted leave of absence for three months on Surgeon's Certificate of Disability. S. O. 231, A. G. O., November 19, 1873.

ALDEN, C. H., SURGEON.—Assigned to duty at Fort Walla Walla, Wyoming Territory. S. O. 157, Department of the Columbia, November 6, 1873.

WEBSTER, WARREN, SURGEON.—Assigned to duty at Angel Island, California. S. O. 133, Department of California, November 4, 1873.

HUNTINGTON, D. L., ASSISTANT-SURGEON.—Assigned to duty at Fort Stevens, Oregon. S. O. 157, Department of the Columbia, November 6, 1873.

KOEFER, E. H., ASSISTANT-SURGEON.—To report by letter to the Commanding General Military Division of the Atlantic, for assignment to duty. S. O. 230, c. s., A. G. O.

STYER, CHARLES, ASSISTANT-SURGEON.—Granted leave of absence for thirty days, with permission to leave limits of Department and apply at Division Headquarters for an extension of thirty days. S. O. 200, Department of the South, November 19, 1873.

WIGGIN, A. W., ASSISTANT-SURGEON.—Assigned to duty at Fort Vancouver, Wyoming Territory. S. O. 157, Department of the Columbia, November 6, 1873.

PHILADELPHIA MEDICAL TIMES.

ORIGINAL COMMUNICATIONS.

NEUROTOMY.

BY S. WEIR MITCHELL, M.D.

THE state of medical opinion as to the results of nerve-sections has undergone some strange reversals from time to time, until of late, owing chiefly to imperfect observation on the part of certain eminent surgeons, we are told that a large nerve can reunite within a few days after having been divided, and can thus early reassume its lost functions. Upon this point, as has often happened, the physiologists and clinicians were on opposite sides. Nerve-sections in the laboratory, even in young animals, gave no such result as the presence of feeling a few hours after the division of a nerve. It is most interesting to observe what occasioned this conflict of opinion, and to see how both sides were somewhat astray, and how the truth—a most useful and practical one—has at last come out of it.

In 1864, the usual physiological belief was, that a nerve having been cut, some definite region to which it was distributed would lose all sense of feeling, and that certain muscles would act no longer until after many months, when, in fortunate cases, the nerve-ends reunited, and the sensory and motor functions became partially or fully restored. In the same year, 1864, Laugier brought the ends of a cut nerve together by suture, and saw that the parts involved had some feeling and motion *the very same day*. As strange results were obtained by Nélaton and Paget. But soon after Verneuil pointed out that in cases where no reunion could have taken place, where, in fact, a post-mortem section showed absence of union, motion had been seen and sensation noted in the parts concerned: so that some of the cases proved too much. In 1867, Letiévant, after dividing the median nerve in man, satisfied himself that both feeling and motion remained, where, according to the ordinary notions, none should have been found. A careful study, however, showed that each muscle fed by the cut nerve was really palsied, and that the motions seen were due to muscles supplied with nerve-force by the ulnar and radial. As to this there can be no doubt; and my own study of a recent case has on this point satisfied me thoroughly. The seeming presence of feeling was more of a puzzle. It was found that feeling was vastly lessened in the median area, but not lost, except in a very limited space: now, this state of things existed within a few hours after the section, when not even the wildest believer in regeneration of nerve could dream it had already taken place. The explanation in this especial case lies in the existence of branches from the ulnar which enter the median nerve below the point of section, and also in the intimate plexus it forms with other nerves at the finger-ends. The anatomists are, in part, responsible for the clinical difficulty. Take for instance Flower's Atlas, or most of the anatomies,

and you will see that the median innervates this area, and the ulnar that, and so on, while in truth this whole surface-anatomy is a fiction and has to be studied anew by closer dissections and by utilizing such nerve-sections as are made in man. In fact, I believe it will be found that the regions of skin made sensitive by but one nerve-branch are very limited, and that throughout the whole surface, and not merely at the extremities, division of several nerve-stems will be needed to extinguish feeling of all forms in any one part of the skin. Strange, then, as it may seem, there is yet room for a careful monograph on the anastomoses of the main nerves. As regards the hand, some of these are pointed out in certain anatomies, and not in others. In Hilton on "Rest and Pain" there are interesting facts in this direction, and so also in Hirschfeld; while Letiévant has described at least one hitherto unnoticed anastomotic branch between the ulnar and the median. Yet later, Arloing and Tripier have shown that in cats and dogs these communications are so complete that to annihilate feeling in any one part of the paw all its nerves must be cut.

I was amazed of late to see how difficult it is in man utterly to destroy feeling in the arm. In a notable case, Dr. Maury divided the whole brachial plexus in the neck. At first the posterior and inner cords were cut, and the patient was allowed to become free of the effects of ether. To my surprise, he still had touch-sense in the palm and dorsal surface of the hand, forearm, and arm, and on the inner face of the arm. The inner face of the forearm I think I did not examine. As to the rest, I am positive that partial feeling remained until, the external cord being divided, the whole sensibility was lost save at the upper parts of the arm, where there was, and still is, some tactile sense, due, I presume, to filaments given off from the plexus above the point of section. I do not dwell on the case, as it will be more fully related at another time. It went far towards justifying the extreme opinion I have mentioned as that likely to become a future medical belief. I had certainly believed, with others, that in the brachial plexus the interchange of fibres was notable, but I had not supposed it to be so perfect. M. Letiévant* and I myself have pointed out some of the fallacies which arise from want of care in studying the true areas of lost feeling; but it is needless to dwell further on this.

I may add that his views as to surface-anatomy of nerves are well illustrated by cases of my own, and that the lapping over, so to speak, of nerve-territories is to be seen in the face as well as in the extremities. Careful study of his facts, and of one of my own which I am about to publish, has shown that the nerve-distribution in the hand is subject to certain variations, so that sometimes the median, for example, innervates the palmar face of the thumb, the index and half of the second finger, sometimes extends over the whole face of the latter, and very often reaches the line given in Flower's plates, which carry it up to the middle of the face of the

* *Traité des Sections nerveuses*, Paris, 1873.

third finger. Also, in my case it gives scarce any surface-feeling to the palm, while in Letiévant's it largely supplies the palm on one side, according to the commonly received anatomy. Its section also greatly damages feeling on the dorsal aspect of the thumb, the index and second finger, but the area affected is not the same in his cases and in mine. Like variety exists as to the ulnar distributions, and, as I shall show in future, the radial nerve has been cut, and has left in one case so large a degree of feeling on the dorsal face of the hand that neither the patient nor the physician could perceive that there was any loss at all.

It is to be hoped that a few years will give us a large number of careful maps of the regions in which feeling is lost after nerve-sections. If they are made by observers as careful as Letiévant, we shall have, by-and-by, a new and reliable surface-anatomy. It is greatly needed. Nor do we require to know alone the ordinary distributions: we desire also to have sketches of the variations which seem to be frequent, for while as yet nerve-supply to muscles seems to be definite and constant, that to the skin-spaces appears to vary strangely and frequently.

I have said that there was practical value in this knowledge; as thus: a year ago, if a surgeon had been asked to cut a nerve to relieve a local injury on the extremity of the dorsum of the index-finger, he would, without doubt, have cut the radial; and yet, as we now know, the median may have been equally or more to blame. Doubts of like nature would arise if the cause to be quarantined by nerve-section lay in the third finger, because sometimes that part is fed by the median, sometimes by the ulnar, at times by both. In these facts lies, as I believe, the true blame for many of the failures to relieve by nerve-sections epilepsy or tetanus when these are due to an eccentric cause. The knowledge I am seeking becomes, from this point of view, of inestimable value.

I have asked myself again and again how it is possible to know just where a given nerve is distributed,—whether it chances to be normal, or one of those cases of variety which occur so often that we may well call them normal variations. There are, I think, three ways. If we freeze the ulnar, it is not difficult, as a rule, to determine by the lost feeling its area of distribution. The process is very painful, as I know to my cost. Pressure may also be used, and is more generally applicable. We can compress any of the arm-nerves until they lose power to transmit impressions, and then the area of lost feeling may be studied. This also is not a painless process, and it is not always or everywhere of easy application. In my own case I can easily trace out the distributions by passing a faradic or galvanic current through two or three inches of the nerve to be studied. I think the plan will usually answer. It gives very clear replies. Thus, a current of moderate intensity is felt only in the usual ulnar region, *i.e.*, up to the middle of the third finger, but most sharply in the ulnar palm and the little finger; made more severe, it is felt also in the third finger, and even beyond it; but a mild current

surely placed in the ulnar or the median gives clearly a sense of vibratory tingling in certain spaces. As to the interpretation of the results of very severe currents I am not so sure; they seem to affect nearly all of the hand; but as to this I shall probably have more to say in future.

M. Letiévant discusses in his excellent treatise the question of neurotomy for cancer, ulcers, tetanus, neuralgia, and epilepsy, but says no word as to its use in local spasm, as blepharo-spasm, in which I have seen brilliant successes and as remarkable failures. As regards neuralgia, I have had to counsel in favor of neurotomy where the pain had a traumatic cause, but in what I may fairly call a vast experience I have never been driven to cut a nerve for common neuralgias. Anstie does not even discuss the question; and it is to be remembered that galvanism has succeeded after neural section has failed. Yet I should not hesitate to use it, because I believe that even when the cause is of known centric origin there may be good reasons why neurotomy may cure. Indeed, we ought not to fail to remember that galvanism is a peripheral application, and does win successes, even where the malady is surely centric.

As regards the influence of nerve-section on the thermal conditions of a limb, the clinical observers tell us that there is always a fall of temperature, while the physiologists say there is a rise of the thermometer; but the latter observers experimented immediately after section, the others, as a rule, only after weeks or months, so that I felt free to predict that when the clinician would put himself in the same position as the physiologist, nature would make him the same answer; and this is just what my own cases have lately taught me. First, the temperature rises, and then, after a time, it falls. These constant conflicts of opinion always end in this fashion. Somewhere there has been a defect of observation, or else the stand-point whence the facts were seen has been different, and so the facts have been made to seem to vary. The case of neurotomy of the brachial plexus by Sands and Seguin* is, I suspect, the first example of this operation. It is admirably related, with scarcely any defects, which cannot be said of the European cases of neural section. In fact, as I have already said, the horrible confusion as to the results of neurotomy, which has so long embarrassed us, is due to observations so clumsy and imperfect that they cannot be too severely criticised.

KITCHEN MEDICINE.

BY J. SOLIS COHEN, M.D.,

Lecturer on Laryngoscopy and Diseases of the Throat and Chest in Jefferson Medical College.

KITCHEN Medicine is a term which will serve to express what is so significantly styled *Hausmittel* (literally house-means, or home-remedies) by the Germans. The resources of a modern kitchen are so vast that, with due attention to them, at least

* A Case of Traumatic Brachial Neuralgia. New York, Jan. 1873.

in the more ordinary forms of disease, or ailments rather, which form the bulk of a physician's practice, the intelligent practitioner can often practise therapeutics without drugs. It would be impossible to exhaust the subject in the course of a journal article, especially if one permitted himself to dwell upon the collateral subjects that such a theme would naturally suggest; and no attempt to do so will be made on the present occasion. The writer has had it in view for a long time to write a volume, to be entitled *Therapeutics without Drugs*, which should treat in a scientific manner of the remedial agencies of air, water, heat, cold, food, clothing, exercise, rest, *kitchen medicine*, and so on; without reference to a single drug of the hundreds that crowd our *materia medica*, or the slightest resort to a pharmacopœia.

The potent remedial virtues of drugs are by no means to be ignored. Instances are frequent enough in which it is impossible to treat disease without their aid. Still, it is well now and then to have our attention directed to agents which are apt to be overlooked because they are so familiar, and undervalued because they are easy of access.

If we take a cursory glance at some of the familiar articles to be seen in the kitchen, and reflect upon a few of the therapeutic uses to which they may be applied; if we reflect upon the nature of the physiological effects which it is the object of therapeutic agents to promote, and look in the kitchen for means to accomplish them; or if we run over in the mind a list of the most frequent ailments to which the human body is subject, and hunt mentally in the kitchen for means to obviate or relieve them, we shall find an efficient armament not at all to be despised. Every physician is fully aware of all this: yet such is the force of habit that it seems more professional to write a prescription and order its administration so many times in the twenty-four hours, than to recommend recourse to some simple or familiar measure which would answer an equally effective purpose. Our patients themselves are much to blame for fostering this habit. If a physician is called in because some member of a family has caught cold, to take a familiar example, and orders the patient to put the feet and legs into warm water, to go to bed and wrap a wet towel about the neck, and to abstain from meat, spices, coffee, and tea, for a day or two, *materfamilias* jumps to the conclusion that nothing is the matter, that she has been unnecessarily alarmed, and she begrudges the pecuniary acknowledgment that she will have to make in consequence. Many a physician has had the money value of some of his visits questioned "because he did not prescribe medicine." Ten to one, the next time a member of her family is ill, the economic matron will try her own hand at home-remedies, and, ignorant of the principles that actuate her medical attendant in their selection, will run the chance of doing something injurious instead of beneficial. Physicians, however, must be true to their calling, and suffer the imputations to which ignorant or thoughtless patients subject them.

It is almost superfluous to instance the success of the homœopathic treatment as an example of the good

that can be accomplished without drugs; but we who cannot recognize any inherent efficiency in infinitesimal doses of medicines cannot look otherwise upon this practice.

Bread pills were fashionable at one time in the treatment of trivial complaints, the doses being given to quiet the apprehensions of the invalid, and the regulation of diet and of exposure, with resort to some of those practices which we designate as kitchen therapeutics, being depended upon as the direct remedial agencies. Many an apparent elaborate prescription is composed at the present day for similar purposes, in cases where it is expected that the physician should "do something," and where he feels that the step is superfluous. It is true that mental therapeutics is sometimes a necessary element of treatment; but it is a shame that we have to resort to unuttered deception in the science of healing.

Dilutents are often called for in the practice of medicine, and many of the articles used for this purpose owe most of their benefit to the water in which they are administered; and water alone, impregnated, it may be, with some kitchen remedy,—as currant-jelly, or even barley, for example, in simple erythematous sore throat,—will be just as valuable in many instances as a pharmaceutical extract.

Emetics are often called for, and in many cases mustard-and-water is just as valuable as sulphate of zinc or copper, or tartar-emetic, and so on, and sometimes more so.

In cases of severe cramp in the intestines, dry heat applied from the door of a range or furnace, taken off and wrapped in folds of flannel to protect the skin, will often give prompter relief than a dose of opium. The mustard-plaster, so much in vogue and so very efficient as a topical remedy in many affections, is a familiar example of the value of kitchen medicine.

The use of table-salt in restraining hæmoptysis, and even the use of oil of turpentine, may be instanced as further examples. Cayenne pepper will do as good service in certain affections, as in bowel-complaints, or used as a gargle in sore throat, or taken in spirits of some kind as a preventive of the deleterious effects of exposure to malaria, as many other remedies more frequently prescribed. Vinegar comes in use as a local application very often: it is good to impregnate a sponge both to allay excessive action in the skin in fevers and in the sweats of hectic. It is often as good internally, in some form or other, as are other acids, mineral as well as vegetable, to assist digestion in certain varieties of dyspepsia. It is often as good an ingredient in a gargle as any other acid, and very often the best inhalation that can be given in certain inflammatory conditions of the respiratory passages. Salt-and-water is an excellent tonic to the skin; an efficient laxative in moderate costiveness, judiciously managed, better often than any saline purge; the very best and least injurious substance to use in the nasal douche to detach the accumulated secretions of certain forms of catarrhal inflammations of the nasal passages. Spices of various kinds are splendid

carminatives internally administered, and, quilted between folds of flannel, they form an excellent bandage to be worn over the abdomen of patients subject to bowel-complaints. Dry salt similarly quilted between folds of flannel, and heated before a fire, retains heat a long time, and is an excellent application in painful conditions of the bowel.

Cucumbers, cabbage, tomatoes, fruits of various kinds properly selected, unbolted flour, milk, calves' brains, sweet-breads, oysters, terrapins, certain kinds of fish, and other articles of ordinary or occasional diet, contain certain ingredients, in far better elaboration than the skill of the pharmacist can prepare, which can often be utilized for supplying deficiencies in the economy in the treatment of chronic disease.

Milk, lard, and sweet oil applied to bruises, to harsh skins, or used for anointing the body in scarlet fever and the like, are often of the greatest value. In chronic ulcerative laryngitis entailing dysphagia, the preliminary deglutition of a little sweet oil will often protect the parts from the mechanical irritation of food, and render swallowing more efficient and less painful.

In this manner a great number of examples could be collected of the efficiency of kitchen medicine. The more it is resorted to, the less will we depend upon drugs, and the simpler will be the art of prescribing medicine.

The list of drugs is enlarging so rapidly, new remedies are so crowding older ones out of use, that it is well, once in a while, for the practitioner to reflect upon what can be done, in suitable cases, without resorting to drugs at all.

TINEA SYCOSIS.

BY GEORGE G. WOOD, M.D.

TINEA SYCOSIS, or what is popularly called "barber's itch," when met with in its true form is usually very hard to cure. I have thought proper to submit to the profession, through the medium of your journal, the two following cases which occurred in my own practice:

Case I.—G. D., a farmer, aged 26 years, came to me suffering from "barber's itch" contracted about one month previously in a barber-shop. He complained of an itching, burning sensation on the chin. His chin was covered with small pustules, which, on being opened, discharged a thick tenacious matter that dried into crusts. The pustules I found, on close examination, to be the inflamed hair-follicles, and on plucking out the hairs they presented a frayed appearance at the roots, like the strands of a string, which is unmistakable evidence of a parasitic disease of the hair-follicles.

For treatment I tried, in rotation, white precipitate ointment, weak solution of corrosive sublimate, citrine ointment, sulphite of soda, and, in fact, all the parasitic remedies at hand, but without avail. He came back each time complaining that the disease was growing worse. Looking through Niemeyer's Practice, I found his treatment of sycosis so peculiar that I determined, as a last resort, to try it in this case.

First I removed all the crust or scab, by softening it with glycerin, next had him shaved as close as pos-

sible. I then took my little sharp-pointed bistoury and opened every pustule that I could find. Where the pustules were confluent, I made cross-incisions through the clusters. Like the shaving, this scarification was not nearly so painful as might be supposed. I next touched each opened pustule and cluster of pustules with a very strong solution of corrosive sublimate, made by dissolving one part of the sublimate in two parts of alcohol. During the night I had the part covered with a rag thickly smeared with white precipitate ointment. I repeated this process every day on the new pustules as they appeared. At the end of a week he was completely cured.

Case II.—J. R., tailor, aged 45, came to me suffering from "sycosis" of six weeks' standing. Symptoms the same as Case I., with the exception of the disease being confined to upper lip. He had consulted other physicians without avail. Not feeling like subjecting him to the rigorous and somewhat painful treatment of Niemeyer, I tried the usual list of parasitic remedies, as stated in Case I., but without the least favorable result: so at last I adopted Niemeyer's treatment, as in the other case. At the termination of one week he was entirely rid of this loathsome disease.

It only remains for me to say that I am perfectly satisfied with this method of Prof. Niemeyer's as the surest and quickest that I know, and so I would recommend it for trial by other physicians. The disease destroys the beard so fast that we need a quick means of curing it.

MUNCY, PA., November 11, 1873.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. H. C. WOOD, JR., OCTOBER 8, 1873.

Reported by JAMES C. MERRILL.

TRAUMATIC OBSTRUCTIVE COLITIS—ANTIPHLOGISTIC ACTION OF MERCURY—RECOVERY.

ANDREA MOLARAWITZ, German, aged 30, was admitted into this hospital on October 1; states that one week before admission, while trying to stop a runaway horse, he was violently struck in the left iliac region by the shaft of the carriage. He suffered much pain for several days, and noticed that his bowels became obstinately constipated after the reception of the injury, and for this cause applied for admission here.

On admission he had much pain in umbilical region; belly very tympanitic, breathing diaphragmatic and rather labored. He was ordered a house injection and oil. This having no effect, he was ordered during the next two days several doses of oil, Epsom salts, and an injection of lime-water and oil. Croton oil was administered in divided doses, and, these having failed, a forced injection of two gallons of water. The battery was finally applied, and some hours after the use of the induced current the man had three or four small passages at short intervals. Since this time his bowels have not been open, he has suffered much pain, and has taken no food.

As the man lies before you, you see that his belly is swollen and tympanitic. Notice particularly that pressure on it gives him no pain, so that certainly there is no acute peritonitis. There is now a slight fulness in the iliac region, and two days ago faint localized dullness was detectable on percussion, and there was decided but not excessive tenderness over the swelling. Our patient has not vomited since admission, and passes an ordinary amount of urine.

Our patient has at no time suffered much, but what pain he has had has been referred to the umbilicus instead of to the seat of injury. This is very apt to occur in intestinal diseases. In short, gentlemen, obstinate constipation is the most marked symptom of the case: for the large amount of purgative medicine has had but very little effect.

What one of the usual causes of protracted constipation is present in our patient? We may reject external compression of the bowels, as from cancer or some enlarged gland outside of the intestine, and constriction, as from cancer, etc., in the intestinal walls, because in these the constipation comes on slowly and gradually increases, and the feces are long and ribbon-shaped. Among the causes of acute constipation strangulated hernia is not infrequent, and I would warn you to be constantly on guard and insist upon a most thorough examination in every case resembling this. In this man we can find nothing to justify such a diagnosis.

Large gall-stones arrested in the intestines may produce symptoms analogous to those now present in the patient before us; but constipation from such causes is always preceded by severe bilious colic, which has not occurred in the present case. Hard foreign bodies are occasionally swallowed and cause constipation; but this is rare except in children, and has not occurred in this instance. Incarceration, when the bowel is bound down by bands of false membrane, as after peritonitis, has obviously not taken place here, because there has been no antecedent disease of such nature. The three most common causes of such symptoms as those of this man still remain for our consideration.

Fæcal accumulation is by no means rare: indeed, if you are called to a case similar to this, but with a history of chronic constipation, you may almost take it for granted that this is the cause; and, even if a history of diarrhœa is given, do not fail to assure yourself as to the absence or presence of a fæcal mass. The most common seats of this accumulation are just above the sigmoid flexure and low down in the rectum: if in the former position, an indistinct tumor is usually detectable by palpation or by dullness on percussion; if in the latter, digital exploration of the rectum will reveal the cause. This man, on his admission, was treated for fæcal accumulation, but, as you see, without success; nor can an impaction of feces be detected by the means just mentioned; and I think the exciting cause of his protracted constipation is more serious, being either *invagination* or *enteritis*.

Invagination, in which the bowel is forced into itself like the finger of a drawn-off glove, at first permits an occasional passage of feces, or even allows of diarrhœa; later the œdema may cause such swelling of the coats of the bowel as to totally obstruct the canal. The characteristic symptoms are a sudden onset, vomiting, pain usually intermittent and not very severe, more or less complete constipation, and after a time passage of blood *per anum*, from rupture of the congested obstructed vessels at the seat of invagination. The vomiting may even precede the pain and constipation: it consists at first of ingesta, is then bilious, and later still stercoraceous. The latter generally indicates occlusion, and is always a very unfavorable symptom, particularly in males; in females it is sometimes caused by hysterical intestinal spasmodic occlusion. A tumor is usually detectable.

In the case before us all the above symptoms are, or have been, present, with the exception of vomiting and passage of blood *per anum*; and the question arises, Does the absence of these signs warrant us in rejecting the diagnosis of invagination? By exclusion we have already arrived at the diagnosis that the patient is suffering either from invagination or enteritis. Remem-

ber, the history dates back to a traumatism of the part, and the position of the lesion is the favorite position of obstructive enteritis,—the neighborhood of the sigmoid flexure.

Vomiting is as much a symptom of enteritis as of invagination; but its severity in either case is proportionate to the nearness of the lesion to the stomach, and its absence in our patient is probably simply due to the obstruction being low down in the neighborhood of the sigmoid flexure. As invagination is the severer of the two diseases, the probabilities seem to be that vomiting, even when the bowel is affected very low down, would be present more certainly in it than in enteritis. Hence the absence of vomiting inclines us towards enteritis in the present case. The absence of blood from the passages at this late date seems to me of vital importance. I believe it proves that the case is not invagination. If this be so, our patient must be suffering from enteritis, or, more correctly, colitis, as it is undoubtedly the large intestine that is affected.

The diagnosis having been made in our case as traumatic paralytic enteritis or colitis, the question of treatment follows. When the man was first under care in the hospital, he was treated, as you have been told, for fæcal accumulation. If the true character of the disease had been detected at first, leeching over the seat of injury would no doubt have been practised; but antiphlogistic measures were not resorted to until a few days since, when the patient was put upon the use of opium and of blue mass. Yesterday afternoon pyalism was first detected, and simultaneously an improvement was noted, not a sudden marked one, such as follows relief by the action of a purgative in fæcal accumulation, but the slight amelioration of symptoms such as should be expected to follow the action of a drug which lessens the cause of the obstruction, namely, inflammation. The expression of the man's face was much less anxious, the tongue was more moist and less heavily furred, the local abdominal tenderness and the abdominal pain were less. This morning these signs of improvement have increased; last night the man passed flatus spontaneously and freely, and the tympanitis is greatly lessened, and the tumor imperceptible.

Although he has had no stool as yet, I make confidently a favorable prognosis, because by the influence of the mercury the inflammation, the cause of the obstruction, has been conquered. To aid, however, in the production of a stool, a drachm of castor oil shall be given our patient every two hours. Liquid diet, *i.e.*, milk, shall still be freely administered. [The night subsequent to the clinic, four evacuations took place, and the man slowly but steadily convalesced from that time until he left the house, cured.]

TRANSLATIONS.

THE INFLUENCE OF ALCOHOL ON THE TEMPERATURE OF THE BODY.

By DR. FRANZ RIEGEL (*Deutsches Archiv für Klin. Med.*).

OBSERVERS in previous years were accustomed to ascribe to alcohol the power of elevating the temperature of the human body when introduced into the stomach, being led to this conclusion by the subjective sensation of warmth perceived by the subject of the experiment and observation. Observations, however, of later date have led some experimenters to a diametrically opposite conclusion,—*i.e.*, that the ingestion of alcohol into the economy is conducive to a reduction of the bodily temperature. Many of these experiments have been made upon inferior animals; and to these too much authority must not be given, for it is

of common experience in experiments upon small animals to have a marked reduction of temperature consequent upon trifling influences, and in a majority of these cases direct proof of the causation of the phenomena observed by the alcohol swallowed is wanting. In addition to this, the relative quantity of alcohol employed is so large that while the result may be of use as demonstrating the influence of alcohol upon the bodily temperature, it cannot be applied to solving the question as to the use of alcoholic stimulants in the treatment of disease, where small quantities are to be administered through long spaces of time.

For these reasons Dr. Riegel disregards the results obtained from experiments upon the lower animals, and confines his attention to the data of those experiments which have been made upon men, both healthy and diseased.

He deals only with the more important modern researches upon the subject, and with those only which have been conducted with special reference to the alteration in temperature, inasmuch as he has to do not with the special indications for the administration of alcohol, but only with its effect upon the bodily warmth.

Todd and his followers were the first among modern writers who strongly advocated the administration of alcohol in febrile and inflammatory affections. While his doctrines found many advocates in England, America, and France, in Germany they were received with a less degree of favor, due partially to the small number of experiments made to establish their truth or falsity, partly also to the variety of results reached by observers. In all the recent observations a great discrepancy of results is noticed, being, no doubt, partly due to a want of accuracy and frequency in examining and recording the variations of temperature.

The principal object of Dr. Riegel's own investigations has been to note the variations of temperature consequent upon the administration of alcohol in healthy individuals, as well as in those in all stages of fevers and in convalescence. He considers that the effect of the administration of alcohol upon the temperature is the most certain criterion as to the propriety of its use in the treatment of fevers, and if, as some recent investigators have asserted, this is constantly followed by an elevation of the heat of the body, its use can only be justified in the treatment of patients in a state of collapse or of those who have been previously habituated to its employment. If an elevation of temperature consequent upon the use of alcohol cannot be proven, there is nothing from this view of the case to contra-indicate its use, for it is only rational to endeavor by its timely employment to husband the forces of the economy. The argument in favor of its use becomes much stronger if it can be demonstrated that it has the power to produce a diminution of temperature, and that this power is increased by an increase in the amount administered.

Dr. Riegel's experiments number eighty-six, and in each case comparisons were made with the normal temperature of the same individual. The thermometer in many cases was introduced into the rectum as well as the axilla; and, from the discrepancies sometimes observed, the former locality is regarded as the preferable one for observations of this nature. In a majority of the cases white or red wine was employed; in some, alcohol diluted to a greater or less degree. From the observations made under the above conditions upon the first class of cases—convalescents—the following conclusions were drawn: 1. Alcohol, even in moderate doses, in many cases causes a lowering of the temperature of the body. The amount of this diminution averages as a rule only some tenths of one degree. 2. Only exceptionally is there noticed an elevation of the temperature consequent upon the administration of alcohol; not unfrequently, at least after minute doses,

there is no noticeable change. 3. The diminution of temperature in convalescents is, as a rule, less than in healthy subjects, or it may be altogether wanting. 4. In those who habitually drink alcoholic stimulants the depressing influence of alcohol upon the temperature is almost always wanting. 5. The frequent repetition of the doses of alcohol diminishes their lowering effect upon the temperature. 6. The amount of diminution of temperature is directly proportional to the dose of alcohol given. 7. The depression of temperature caused by alcohol is for the most part of but short duration, and the temperature soon returns to its previous grade.

These experiments, then, show that the administration of alcohol to convalescents and healthy subjects, if followed by any change in temperature, gives rise to a diminution in the bodily heat, but they do not justify the conclusion that a like result follows its use in febrile cases. To ascertain the effect of alcohol upon cases of this class, experiments were made upon patients suffering from acute articular rheumatism, typhus, erysipelas, etc., and the conclusions reached do not agree with those previously stated. In conclusion, Dr. Riegel states that the influence of alcohol, given in moderate doses, upon the temperature both in febrile and non-febrile states, is comparatively insignificant, but if any change is produced it is more common to have the temperature lowered than elevated. But, although alcohol cannot be looked upon as possessing anti-febrile powers, yet the proof that its administration does not cause any important change in the heat of the body presents us with a strong argument in favor of its use to prevent the too rapid waste of tissue in febrile affections.

The dangerous elevation of temperature must be combated by the use of cold and the other means at our command. Alcohol meets the second indication, to prevent waste of tissue and favor reparative action.

WILLIAM ASHBRIDGE.

IMPERFORATE HYMEN (*British Medical Journal*, October 18, 1873).—Dr. D. Lloyd Roberts reports the case of a girl, aged 20, who suffered from the effects of an occlusion of the intravaginal orifice by a congenital fibroid-like and unyielding hymen. The abdominal cavity was occupied by a tumor, which sprang from the pelvis, fluctuated freely, was dull on percussion, and extended centrally above the umbilicus and laterally into the flanks. She voided her urine with great difficulty, and only while resting on her hands and knees. She had constant backache and headache, constipation, shooting pains in the pelvis, and a distended and inflamed urethra. She was anesthetized, and a small exploratory trocar was passed through the centre of the imperforate hymen, when a dark treacly fluid showed itself at the external orifice. A large trocar was then introduced, and the fluid allowed to pass through the tube, aided by gentle but firm pressure on the abdomen. Eighty-four ounces were thus withdrawn, and during the subsequent fortnight about twenty more ounces oozed away. In a month the opening in the hymen was enlarged with bougies, and the membrane was still further divided. The only unfavorable symptom in the progress of the case was the occurrence of some abdominal pain and tenderness, with general pyrexia, about four days after the operation. This trouble was due to a cessation of the discharge, which had also become offensive: it passed off as soon as the flow was re-established. Dr. Roberts considers this as illustrative of the cause of death after most abdominal and pelvic operations, which he believes to be septicæmia, and not, as generally supposed, metritis or peritonitis.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, DECEMBER 6, 1873.

EDITORIAL.

WHITHER ARE WE DRIFTING?

AMONG the signs of the times which it behooves those who are interested in the reputation of our profession to watch, is the treatment of the medical staffs of our hospitals by the boards of managers. "Honor the physician" was, according to all accounts, a well-obeyed maxim in the days of our fathers; but now the high and mighty potentates who make up the governing boards too often appear to think that physicians are simply their artisans, porters, or draymen, to move at their bidding,—their pawns, to be placed here and there as whim or motives of policy may dictate.

Formerly, the attending physicians were looked upon as co-workers for the common weal, equal in right and in service with the managers themselves,—co-workers to be consulted, not insulted,—co-laborers whose brains and especial training gave them a right to speak and gave weight to their spoken words.

Now, when a revolutionary movement is contemplated, when a motion, perhaps owing its origin to the zeal without knowledge of some nervous trustee, takes shape, the staff find their notices in the morning paper on their breakfast-tables. A very recent and seemingly a very flagrant instance of this grave breach of courtesy is seen in the action of the Board of City Trusts at their last meeting. "Whereas," says the newspaper minute, "Whereas, ministering to the bodies of the poor, with the view of affording them relief from suffering, is a work of mercy

eminently proper for the Lord's day; and whereas, it frequently occurs that incessant labor through the days allotted to work is necessary, either from poverty or from the undue extortions of employers, thereby causing the neglect of the ailments of the eye: therefore, *Resolved*, That the Committee on Minor Trusts arrange with the surgeons to have the Dispensary at Wills Hospital open from two to three o'clock on each afternoon, including Sundays, from January 1, 1874, for the treatment of the eye."

The passage of such a resolution without consultation with the staff of surgeons was, we repeat, a grave breach of courtesy. What is involved? Simply this: that men who have toiled through the week, who have, perhaps, arranged their time through six days that they may have a few hours of quiet on the seventh, shall yield this too, and toil on, worse than the treadmill drudge, who has his day in seven. Simply this: that men who have daily given hours of work to charity shall strip themselves of their weekly dole to their wives and children. In truth, it was a grave breach of courtesy. The men thus ordered without consideration are in every way the peers of those whose thoughtlessness has forgotten their claims; and yet not a man of that board would have ordered his hired employees to give their labor on the Sabbath in such an off-hand manner as is demanded the unpaid labor of the physicians.

This action of the board was, however, not merely a grave breach of courtesy, but, to our thinking, also a great breach of good sense, and seemingly that which has been said to be worse than a crime,—a blunder.

In the first place, the medical staff of the hospital know far better than do the Board of City Trusts the wants of the poor. The difference is that which lies between the theoretical knowledge that comes from riding from hospital to hospital board meeting, from organizing charities, from doing what is perhaps most excellent and praiseworthy work, but work personally distant from the poor, and the practical knowledge which comes from daily personal contact, from visiting the poor in their homes, from hours spent by the bedside of the sick in the hospital. Surely it would have been but the dictum of common sense to consult with the men who had this knowledge before entering upon a measure which is almost unheard of in the annals of Philadelphia charity. In the second place, it is well to "look before you leap." We do not know what measures the staff will take,—we understand, however, they will offer a strong remonstrance at the next meeting of the Board of City

Trusts,—but this we do know, that if they refuse to perform the duty they cannot be compelled, and the Board of City Trusts cannot help themselves, since there are not enough oculists outside the staff in the city of Philadelphia to organize a new service, even if our specialists were so devoid of self-respect and of professional *esprit de corps* as to accept positions under such circumstances.

PROFESSIONAL ADVERTISEMENTS.

IN our late editorial upon the above subject we hastily included St. Mary's Hospital in the list of sinning institutions. Further inquiry has satisfied us that it has preserved its virginity unspotted.

A member of the medical staff of the Wills Hospital has called upon us to ask correction of an error which we inadvertently made in including the name of that institution among those which advertised their staffs. Formerly the hospital did so, and we were not aware that the custom had been discontinued. The same informant tells us that in the discussion which occurred at the time of discontinuance, the defence of the advertising was that "Pennsylvania Hospital did it." The more this matter is investigated, the more the responsibility is seen to rest upon the Pennsylvania Hospital; and one thing seems certain, if the medical staff of that institution will request the discontinuance of their advertisement by the board of managers, the battle will be won,—a great and widening breach in our profession will be healed. We trust that they will do it.

We have another word to say on this matter,—this time to the "contributors" of the hospital. The hospital needs funds. "Our beds are empty," we are told, "for want of them, and the poor are suffering." In the name of charity, we say to the wealthy, Give; but in the name of justice we ask, Is it right to put the money given for the healing of the sick into the pockets of the newspaper-owners? Why should a hospital be advertised at all, especially a hospital so well known? If advertised, why should there be more than a mere announcement? We do not know exactly how much money is at present spent in parading the names of the medical staff before the people, but we are informed, on what seems to us undeniable authority, that not long since the hospital was advertising at the rate of four thousand dollars a year. Ten empty beds in the hospital! Ten suffering sick in the city!

WE feel assured that the amount spent in advertising was reduced so soon as the managers comprehended how enormous it was. But the same principle is involved in spending one thousand dollars as in spending four thousand dollars. Those in need of hospital aid will certainly find out the boon if it be simply offered them. It must be only the very, very poor and ignorant of our city who, in the hour of sickness or of mortal injury, have not light enough to see the portals of the old Penn Hospital looming up in the distance. Such persons, however, do not read the high-toned papers in which much of this advertising is done, if indeed, as is more than doubtful, they read any papers at all.

We can perceive only one class which is reached by these advertisements. Merchant Longpurse, whose maid-servant is ill, looks into his morning *North American* to see who is on duty at the hospital, that he may send his coachman across the way to get a note of admission, rather than to trouble him to go to the hospital with the girl in regular form. We wot not, however, that this is really any advantage to the hospital or heals in the least the sufferings of the really poor who languish outside because the institution has not funds to receive them.

SIR HENRY HOLLAND died at his residence in London on his eighty-sixth birthday, the 27th of October, having just returned from an extended continental tour. It will be long before a successor possessing his varied accomplishments, and combining, as he did, profound medical knowledge with literary and scientific culture, will be found to fill the void which his death has left in the profession. A highly successful practitioner, commanding not only the love and respect of his patients, but also the esteem and affection of his medical associates, an indefatigable and adventurous traveller over three continents, a facile and prolific contributor to the higher periodicals and to the library of his profession, and, withal, a brilliant and fascinating ornament to the refined society in which he mingled, he has been the Admirable Crichton of our century, and has won for himself an enduring niche in the history of his time, and a warm place in the hearts and memories of those who survive him.

He graduated at Edinburgh in 1811, having visited Iceland and written his thesis on the maladies peculiar to its people in such a manner as to call forth many compliments from his examiners. Settled in metropolitan practice, his many endearing qualities, his happy blending of confidence with reserve, his instinctive knowledge of the world,

and his charm as a companion, added to his great professional skill, soon achieved for him a success which secured him at once a competence and undisputed social and literary position. Although, with rare self-denial, he limited his practice so that its earnings should not exceed five thousand pounds per annum, and thus secured to himself two months out of every twelve for foreign travel, and additional time in which to prosecute his favorite scientific studies, yet it is said that he leaves a fortune of about nine thousand pounds a year.

The fruits of the hours thus set apart have long been familiar to the profession. The acute philosophy of his "Medical Notes and Reflections," the logical clearness of his classic treatise on "Mental Physiology," and the vivid, comprehensive portraiture of the diplomatic, artistic, and literary world of the last half-century, contained in his "Recollections of Past Life," are all well known to medical readers.

Eight visits to America rendered him familiar with this country, of which he always wrote in friendly terms; and he speaks with enthusiasm in his last publication of the pleasure with which he had journeyed for two thousand miles along the St. Lawrence, navigated the waters of the Upper Mississippi, followed the Ohio, Susquehanna, Potomac, and Connecticut Rivers far towards their sources, and enjoyed the lakes, waterfalls, and mountain-gorges of the Ottawa.

His multifarious occupation of course left him but little time for purely professional business. He was never connected with a hospital, he never held office in the College of Physicians, nor was he ever seen in public medical circles; yet no name was better known in polite society, and he numbered among his intimate friends all who were distinguished as wits, scientists, or *littérateurs*.

Few men have led so active and yet so equable and happy a life, few men have so well united in themselves the social and professional qualities which should adorn the typical physician, and few men have been so widely and sincerely mourned for, as Sir Henry Holland.

"OUR Boston cotemporaries" have replied to the *British Medical Journal* in regard to the death from ether reported in the issue of October 11 of that journal. The form of the answer is as a letter from Prof. H. T. Bigelow. He says,—

"A feeble boy was etherized. During this process, though only partially narcotized, he was very completely asphyxiated, and, when nearly dead, was oper-

ated on without efforts at resuscitation. When at last his absolute prostration awakened serious alarm, he was vigorously flogged, with the view of restoring his exhausted strength, and under this active stimulus was excited to a final muscular effort, which expended and extinguished his flickering vitality. I believe that such a death might have occurred without the ether."

Afterwards he analyzes the case in such a way as to seemingly prove the correctness of his view.

IN England, as is well known, people, unlike the Americans, object to eating adulterated food, and there is a system of government inspection, with heavy fines, and even imprisonment, for those detected in selling such adulterated articles. According to the *British Medical Journal* of November 15, the bakers of Shoreditch Vestry, London, have been a little too much for the official analyst, Dr. Stevenson, Examiner in Toxicology to the University of London. They set their snares and nets so skilfully as to metaphorically land him high and dry, floundering about to no purpose. Loaves of bread of undoubted purity were labelled by him officially as being probably adulterated, whilst one loaf in which a drachm of alum had been purposely put received the official commendation of "not adulterated."

CORRESPONDENCE.

FORT SNELLING, MINN., November 24, 1873.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES.

IF sponge tents are coated with oleum theobromæ, their roughness disappears, and their introduction is not unpleasant.

Very respectfully, your obedient servant,

M. PENHOEL.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, OCTOBER 9, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. WILLIAM PEPPER exhibited, for Dr. MACKENZIE, of Conshohocken, a specimen of *carcinoma of the liver* from a child *eight weeks* old, born of healthy parents who had two healthy children and a fourth who was the subject of epilepsy. The father was about 40 years old, the mother 36. The child seemed well at birth, took nourishment well, and was always a good child; it continued well, taking nourishment regularly, nor was there any increase in the size of the abdomen, up to ten days before death. The enlargement of the abdomen was firm and hard, and there was no sense of fluctuation; it increased rapidly, and there was increased prominence of the cutaneous veins. There

was no jaundice, no emaciation, no cachectic appearance. The only marked symptom was pain, which caused the child to cry out, and seemed to be increased when the body was turned to the left side. The urine was normal, and the stools were natural, though greenish at first.

At the *autopsy* the lungs and heart were found healthy. The stomach was healthy; the kidneys were not examined. There was no peritonitis, but about eight ounces of mixed clotted and fluid blood lay in the abdominal cavity. The clot lay over a large mass springing from the substance of the liver at a point of rupture.

Liver.—Weight, 11 ounces, 307 grains; entire organ measured six inches in transverse diameter. There were no evidences of inflammation of its capsule, which was smooth over most of the organ. The bulk of the organ was yellowish in color. The *right lobe* was free from any morbid growths, and of normal shape. The gall-bladder was healthy, and the biliary passages were free. The *left lobe* of the liver was the seat of a large, rounded growth, which occupied its entire extent, projecting from both the upper and lower surfaces. The tissue composing this mass appeared dark, in places almost blackish, through the capsule. It was three and one-eighth inches across, and two inches thick. On the antero-superior part of the growth was a ragged, softened, and torn area, about one inch in diameter, where the peritoneum was ruptured and partially destroyed. On section, the tumor presented the characteristic appearances of hæmatoid cancer.

Portions of the tumor were sent to Dr. TYSON for examination, who returned the following report: "I have examined the morbid specimen, and find it made up of a rather large-meshed stroma, filled with blood-corpuscles and cells, of which the accompanying drawing exhibits types. They are mostly pale, faintly granular, and generally contain one indistinct nucleus. Comparatively few multinuclear cells were present. Others of the cells were more highly granular, and others completely fatty. Some free oil also was present. There were very few pigmented cells, the coloration being mainly due to blood, of which there was a great abundance and apparently outside the vessels, as none of these were seen in sections treated with acetic acid; though it does not follow from such examination that the tissue was not extremely vascular. Indeed, I incline to believe it vascular. The piece of liver of more normal appearance was highly fatty, many cells being completely filled with oil, of which there was also an abundance free floating. The cells were more numerous in relation to the fibrous tissue, and more numerous than in the morbid portion."

Dr. PEPPER remarked upon the rarity of this affection in young children, and that the localization of cancer in them was very singular. Cancer of the kidney, for example, is relatively common in children under two years; there are also a certain number of cases of cancer of the glands; but other forms are rare.

Dr. BERTOLET asked whether the tumor was not very vascular. He said that if it was an *angionoma* taking on cancerous change secondarily, the case would be more consistent with experience, since this form of tumor is not very uncommon in children.

Dr. TYSON said that, although the mode of examination he had employed had not revealed any blood-vessels, he had, nevertheless, thought it likely that the tumor was rich in them, not only from its gross appearances, but also from the large number of corpuscles which occupied the meshes of the stroma.

Dr. PEPPER said that the history of the case was peculiar in this, that the development of the growth was very rapid, and that there was no cachexia.

The specimen was referred to the Committee on Morbid Growths, who reported it to be one of *carcinoma*.

Dr. H. LENOX HODGE presented a *large fibro-cellular tumor of the lower extremity*, measuring around its base 37 inches, over the anterior surface from above downward 27 inches, obliquely 37 inches, and laterally 35½ inches; removed a week ago, by amputation through the middle third of the thigh, at the Presbyterian Hospital, from a colored woman, 28 years of age. She states that as long as she can remember she has had an enlargement over the front of the knee; that it has gradually grown until it has attained this great size. She is the mother of four children, and, until a month ago, was able to take care of her children, attend to all her household duties, and at times she went out to do a day's work. She has not had pain in the tumor, but has only suffered from its great size and weight. The base and attachments of the tumor extend over the front of the thigh as high as the middle third, and around the outer side to the posterior surface, and across it to the inner side of the popliteal space. On the leg below the knee it was attached to the upper fourth; but when the patient stood the tumor hung pendulous, so as to reach nearly to the ankle. The surface was irregular, and in places lobulated. On the inner side the patella could be felt, and a sense of fluctuation detected. On section the tumor presented a dense fibrous structure, bathed with a clear limpid fluid and traversed by numerous large veins or sinuses. Many of these were large enough to have received a finger into their interior. The arteries were branches from the articular of the popliteal and the anastomotic of the femoral. They were little larger than normal. The knee-joint was distended by nearly a quart of straw-colored fluid. The cartilages covering the patella and tibia and the condyles of the femur were ulcerated; yet the patient, with this condition of the knee-joint, and notwithstanding the great weight of this large tumor, was able to walk and to labor. Several gentlemen of this Society have examined the structure of the tumor microscopically, and Dr. BERTOLET has kindly sent the following note as embodying the result of his observations:

"DEAR DOCTOR,—The tumor is a *sarcoma*. Although different sections show great variations in structure, yet the prevailing type may be put down as the small rounded. In numerous places the cells assume a larger habitus; here and there giant cells are seen. Stellate and spindle cells are also met with. The fibrillated interstitial substance is in many places so richly developed that the cellular elements are nearly lost sight of. It is this condition that gives the comparative firmness to the growth and renders the prognosis less unfavorable than in the softer varieties; yet repullulation may be expected even in a growth presenting these characters.

"The preponderance, in many places, of the fibrillated structure would warrant the designation of fibro-sarcoma; but this term, as well as that of fibro-plastic or fibro-cellular tumor, is also liable to lead to confusion.

"Truly yours,

"R. M. BERTOLET.

"October 8, 1873."

A dissection of the tumor has been made, showing its vascular supply and its attachments. Its origin appears to have been from the subcutaneous areolar tissue, with attachments to the deep fascia. The patella was found to have been laterally displaced, so that its upper or anterior surface presented inwards.

Since the operation the patient has done very well, and is now able to sit up in bed (Nov. 1).

Dr. BERTOLET said he had examined sections from the most dependent part of the tumor. He thought the result interesting as bearing upon the origin of the growth. If the giant cells are to be considered, as contended by some, as migrating from the bone-cells, then it might be said to be highly probable that the

growth emanated from the cambium layer of the periosteum, a site very rich in myeloplastic cells. This point could, however, only be ascertained when a more complete division of the growth had been made.

Dr. T. B. REED asked Dr. BERTOLET whether it was possible that this tumor could have originated from an enlarged bursa.

Dr. BERTOLET replied that such an origin was possible, but, judging from the microscopic characters presented, he thought this tumor did not so arise; that it started more probably from a bony layer; that if it had started from a bursa it would more likely have exhibited more of the lipomatous character, or simple sclerosis of the connective tissue,—the latter condition and the lipoma arborescens being the most frequent attendants of affections of the synovial membranes.

Dr. DE F. WILLARD had examined several sections of the tumor, and found many spindle-shaped and round cells, but did not discover any giant cells. There was also a fibrillated element, which decidedly predominates, and he thought the growth had its origin in the connective tissue of the part.

Dr. HODGE said in reference to its origin that it seemed to be in the connective tissue external to the muscles. In reference to the possibility of such a tumor originating in a bursa, one of the surgeons connected with the hospital mentioned a tumor which had come under his observation about two-thirds the size of the present one, which he thought was a fatty tumor, but found it really an enlarged bursa of the patella. Dr. HODGE further said that the patient up to the present time was doing perfectly well. She had, however, soon after the operation, extruded a dead foetus, which was in a state of decomposition, apparently dead two or three weeks. She was not aware that she was pregnant, and had stated that her courses had occurred three weeks before the operation.

Dr. JOHN H. PACKARD thought these tumors were particularly interesting in regard to diagnosis, which in this situation offered great and peculiar difficulty. In 1864 he had exhibited to the Society a tumor of the thigh weighing fourteen pounds, removed from a woman, age unknown. Several surgeons who had been consulted declined to interfere, and from a number of creases and cicatrices upon its surface a vascularity had resulted, which gave it the appearance of a malignant tumor. The appearance was truly deceptive, but a careful examination led him to believe that it could be safely removed.

The patient was obliged to carry the tumor in a bag, supported by a strap passing over the opposite shoulder. About six weeks after the doctor saw her, she died of cerebro-spinal meningitis; and in order to get the body into the coffin the tumor had to be cut off. It was sent to him for examination, when he found it to be a simple fatty tumor, which could readily have been removed.

Dr. TYSON referred to the large sarcoma of the thigh presented by Dr. MAURY about two years ago. He thought tumors in this situation were generally sarcomata.

Dr. HODGE asked Dr. BERTOLET whether it was common to have veins so large as those presented in this tumor.

Dr. BERTOLET said he did not recollect any statement to that effect, and had never examined into this point; but the larger the tumor the larger we would expect to be the veins; also that it is very natural for sarcomata to be extremely vascular, and at the same time the adventitia of the vessels are thickened. The favorite sites of these colossal sarcomata are the extremities of the long bones,—the femur, humerus, and tibia. There is also the peculiarity of slow growth, and this further peculiarity, that the lymphatics seem to escape, even when we have metastases in distant organs.

Dr. PACKARD presented for Dr. WM. MOSS, of Chestnut Hill, a portion of *intestine containing enlarged Peyer's patches* from which there had been *hemorrhage, causing death*, from a boy aged 5 years. The following history was furnished by Dr. MOSS:

"I saw the patient October 6, 4 P.M. The history of his attack is as follows. On the night of the 5th he had gone to bed in perfect health and high spirits. In the middle of the night his parents were waked by him, and found him complaining of pain in the epigastric region, and vomiting. The vomiting lasted through the night, but ceased on the morning of the 6th; the pain, which was not intense, abated without entirely ceasing. When I saw him he was pallid, pulse 160 and very weak, extremities cold, pupils much dilated, but sensitive. He lay with eyes closed, occasionally tossing his arms and head, speaking only when addressed, but then answering promptly and to the purpose. He did not complain of pain, but, when asked, always laid his hand upon the epigastrium. I observed no mental confusion; but his mother had noticed, several times in the day, slight and fleeting hallucinations.

"His abdomen was natural to the touch, neither swollen nor retracted, and very slightly sensitive on pressure. The vomited matter consisted of the usual contents of the stomach, with many grape-stones. I gave a guarded opinion that his condition might be due to prostration from prolonged vomiting caused by the indigestible fruit, or that we might be at the beginning of a sudden attack of meningeal inflammation.

"I ordered friction and external heat, and a small dose of sp. æth. comp. Saw him again in an hour; the medicine had been immediately rejected, with a flood of coffee-colored liquid. I repeated the medicine, which was retained. He said that the pain was gone, and that he was comfortable. A few minutes after 8 P.M. I was sent for, in haste. As I entered the room the child breathed his last. There had been no change since I last had seen him until just before they sent for me, when he grew more feeble.

"He had been a perfectly healthy child. Two years ago I attended him in well-marked typhoid fever.

"The post-mortem examination revealed that death had occurred from hemorrhage into the intestine from rupture of a vessel in a Peyer's patch, which had perhaps never completely cicatrized. The immediate cause of the hemorrhage was constriction of a large portion of the ileum by a band of adventitious tissue, through which the intestine passed and became strangulated."

Dr. J. C. WILSON presented a specimen of *perforating ulcer of the small intestine*, from a case of typhoid fever. The patient was a girl, aged 15. Symptoms of perforation appeared on the twenty-third day, and she died in a few hours. Peritonitis was localized to the lower parts of the abdomen. The perforation was oval, about three lines by four, and was situated seven inches above the ileo-cæcal valve. A ring of lymph was deposited upon its margin, both in the inner and the outer surface of the gut. A small quantity of opaque serum mingled with blood was found in the peritoneal cavity.

Dr. R. G. CURTIN presented a specimen of *tubercular ulceration of the small intestine*, from A. B., æt. 24. He had been in the army and navy, and while in these two branches of the service he contracted yellow, typhoid, and intermittent fevers. After leaving the service his health was quite good until about a year ago, when symptoms of pulmonary tuberculosis appeared. This disease progressed slowly until a few weeks ago, when symptoms of severe intestinal disease appeared, which soon caused his death. He had intense pain in the abdomen, with about six stools daily.

At the post-mortem examination, the lungs were

found to be filled with cavities, and along the small intestine from the pylorus to the ileo-cæcal valve, every few inches, large ulcers were found. These ulcers were oval in shape, and measured one and a fourth by three-fourths of an inch, the larger diameter being transverse. In the centre of these ulcers large sloughs were found. The piece shown was the lower part of the duodenum and the upper part of the jejunum. In the specimen the valvulæ conniventes were greatly swollen and red around the ulcers, which, with the dark raised central sloughs, gave the ulcers the appearance of flowers. The mesenteric glands were found to be enlarged.

REVIEWS AND BOOK NOTICES.

NOTICE BY JOHN H. THOMAS, ONE OF THE COUNSEL FOR THE DEFENCE IN THE CASES AGAINST MRS. E. G. WHARTON, OF ATTACKS MADE ON HIM AND HIS COLLEAGUES BY DRs. S. C. CHEW AND P. C. WILLIAMS, AND PROF. WILLIAM E. AIKIN. Pamphlet. Baltimore, 1873.

The literature of the Wharton case seems likely to usurp a whole shelf in the medico-legal libraries of the future. Notwithstanding all that has been written, it seems that all the "facts" have not been so fully and distinctly brought before the public *by the defence* as the cause of truth and justice demands.

The author of the present pamphlet, John H. Thomas, Esq., long well known as one of the leading members of the Baltimore bar, was one of the most prominent counsel for the defence in both the trials of Mrs. Wharton. This gentleman is as proverbial for the suavity of his manners and his courtesy towards the witnesses at a trial as he is for his legal powers. When, therefore, he feels it necessary to take up his pen in vindication of himself, his colleagues, and his profession, from the aspersions of certain professional witnesses for the State, we may be sure there is "good and sufficient cause therefor."

Dr. Williams and Profs. Chew and Aikin have very freely ventilated their personal feelings, after their signal overthrow as "experts" in both trials. Unhappily, they have been betrayed by their disappointment into making most unjust and unprofessional attacks not only on the experts for the defence, but likewise on the opposing counsel, and on Mr. Thomas in particular. The latter, however, having unsheathed his sword, deals most trenchant blows at his accusers, nobly defending the legal profession, as likewise his own associate expert witnesses, who had been so traduced by their opponents.

This pamphlet of Mr. Thomas is doubly valuable because Dr. Chew has appealed to Mr. Thomas, or perhaps it would be more accurate to say has quoted Mr. Thomas as approving of his course; and it establishes certain points whose publicity should forever silence the clamor of those who continue to hunt down Mrs. Wharton—although she has been duly acquitted by process of law—with a persistency unheard of in the history of expert criminal jurisprudence, endeavoring to lay before the public evidences of guilt which were not in the legal testimony. Mr. Thomas distinctly proves gross misrepresentation on the part of Drs. Williams and Chew, and clearly shows that the Philadelphia experts acted conscientiously and without reproach; ay, that the very things in regard to them that Dr. Chew now denounces in such bitter terms were known by him before the experts went upon the stand, and *received his approval*.

Dr. Chew and his colleagues affirm that they were not voluntary witnesses, but were forced to attend upon

the trial by process of law. *They know that this is not true.* The pamphlet before us shows that their actions were voluntary,—so much so that the large claim which they, disinterested men, have made for compensation has not been granted by the Baltimore authorities, "but has been bandied about from the Register of the City to the Mayor, from the Mayor to the State's Attorney, because it was for services *not required and not provided for by law.*" It was they who, when poisoning was suspected, did not, as was their bounden duty under the laws, call the attention of the authorities to it, but made themselves the first post-mortem, and the first accusation, without the sanction or even the knowledge of the authorities.

It was they who dispensed with such trifles as the formulæ of a legal inquest,—a coroner and his jury,—and "took upon themselves the office of State's Attorney, coroner, and expert," and made—also voluntarily—a second and a third post-mortem; voluntarily, because there was no one on earth having authority to compel them to do it. It was they who day by day attended the trials most closely, and sat by the prosecuting counsel, prompting questions for the cross-examination of the experts for the defence. It was they who, as proven at the trial, gave at the time of the sickness of Mr. Van Ness repeated opinions that the chief attack was simply due to heat and exhaustion, and yet swore before the grand jury that the same attack was produced by tartar emetic, and testified on oath at the trial that strychnia was the only possible cause of it.

These men—the source, the very soul and centre, of one of the bitterest prosecutions that was ever waged in a criminal court—now complain that their testimony was reluctantly dragged from them. Having completely failed to sustain themselves before a legal tribunal, they insult the medical profession by attempting to sustain themselves before it by aspersions of their opponents, and by asserting that, although they may have failed to find tartar emetic at two post-mortems, they found it at a third, and have it now. Mr. Thomas proves them guilty of misrepresenting facts. At the trial twice they or their colleagues swore that they had found tartar emetic, but on cross-examination their mistake became painfully obvious. Remembering these things, how can we grant them credence now? Is it necessary to remind any one of the worthlessness of the scientific testimony of men so far committed?

After all is said and done in this controversy, one unquestionable fact remains: If Mrs. Wharton be guilty, Dr. Chew and his colleagues are guilty of a crime against society by destroying the evidence; if she be innocent, by their accusations they have committed an equally grave offence against her. One thing they may be well assured of,—*i.e.*, the world appreciates the fact that their zeal in bringing Mrs. Wharton to justice was equalled only by the ignorance which they displayed in the doing of it.

SEX IN EDUCATION, OR A FAIR CHANCE FOR THE GIRLS.

By EDWIN H. CLARKE, M.D., etc. J. R. Osgood & Co., Boston, 1873.

Many Americans remember with what amused curiosity they first glanced over the list of births in an English newspaper and wondered as to when it was, and how it was, that we as a people came to that definite degree of modesty which allowed us to publish marriages and to suppress the birth-announcements. For in fact there is in America a certain prudishness as to all such matters, so that women who are pregnant are led to conceal it, even if, as is often the case, they do not feel truly ashamed of fulfilling the functions of maternity. In England there is certainly less reserve as to mentioning that a woman is pregnant, or expects to be, or has been, confined. The same modishness has inter-

ferred with the frank admission of the relations of sex to business or professional life, and even to education. Hence it is that all sorts of absurd discussions upon these matters go on daily in our periodicals, with so little allusion to the sexual difference and its consequences that one might well suppose we were merely arguing upon the relative capacities of two tribes of males.

The book before us is an outspoken, manly statement, by a physician of the highest intelligence, as to one, at least, of these mooted subjects. It treats of the defects of our ways of dealing with the education of girls, and insists throughout, in the plainest language, upon the constant recognition in our homes and our schools, as well as in the business of life, of the fact that girls menstruate, and that, as the real purpose of women is to have healthy babies healthfully, so whatever interferes with these ends is wrong in principle,—cruel to the future woman, and impolitic as regards the race. This valuable little bit of plain speech had this origin. Dr. Clarke was asked to lecture to the Woman's Club in Boston; whereupon he spoke to its members certain truths, which stirred up so much talk and criticism that he was led to explain himself at large to the general public. If he be not accused of indecency and the like, we shall be pleasantly surprised. After a clever introduction, in which he laments the failure of our women, he treats next of the social customs and school habits which tend to injure them. Then comes the doctor's relation of the numerous cases which he has seen of women ruined by disregard of the facts of sex and its needs during the years of sexual evolution. Another chapter disposes of that peculiar American enormity,—co-education of the two sexes. This is a chapter which needs to be read in this city, where many estimable people believe in this plan of instruction. Lastly, Dr. Clarke indicates the better points in the European way of treating girls at the age of puberty; and this, too, is a piece of plain talk, which every mother should study with care.

After reading the well-weighed words of Dr. Clarke, his verdict as to the want of motherly watchfulness in America, his strictures on systems of education which bend to no laws of physiology, we shall wait with interest the replies which his book ought to provoke. Certainly no such rude attack, and none so efficient, has been yet made upon the modern plan of educating the two sexes together; nor has he by any means stated all of the objections which naturally arise in a physician's mind. It is, indeed, a subject ripe for discussion.

While giving the warmest praise to the motives which caused Dr. Clarke to write, and to the method and temper with which he has written, there is yet a single matter as to which we should like to add a few words.

Dr. Clarke charges that our women are needlessly unhealthy, and that they are only too often unfit to bear and nurse children; that this is owing to want of attention to the peculiar physiological laws of their sexual development; that this is the fault of their mothers on the one hand, and on the other that it is due to rigid methods of education, which develop the brain at the expense of the generative organs. All of this is true,—only too true; but Dr. Clarke in urging it should, we think, have asked himself whether climate, in its largest sense, has not something to do with the delicacy of our women. We believe that he would have been led to grant that a part of our troubles lies here, and in the fact that a perpetually changing race, renewed daily from Europe, is undergoing acclimation, and that there is every reason to hope that we are suffering in part from unavoidable and transient conditions. In other words, we should merely add to what Dr. Clarke has said, that the climate with its extremes, which make exercise so difficult, is, in that and

other ways, very trying to our young women. In saying this, we should merely be emphasizing what Dr. Clarke has so well stated, because, if in addition to the evils which can be avoided we have to admit others which cannot be, there is only the greater reason for keeping in view all the needs of the girl at her time of fullest sexual development.

S. W. M.

GLEANINGS FROM OUR EXCHANGES.

PHYSIOLOGICAL ACTION OF THEINE, CAFFEINE, COCAINE, THEOBROMINE, AND GUARANINE (*Edinburgh Medical Journal*, October, 1873).—It has hitherto been supposed and stated by many authors that theine and caffeine are inert substances, and that the physiological effects of tea and coffee are not due to these neutral principles, at all events in a state of isolation. From experiments conducted by himself, Dr. Alexander Bennett has arrived at the following conclusions:

1. The physiological actions of tea, coffee, guarana, coca, and cacao are mainly, if not entirely, due to their proximate principles.

2. Theine, caffeine, guaranine, cocaine, and theobromine are powerful poisons, inducing a series of symptoms affecting the nervous, respiratory, circulatory, vaso-motor, and glandular systems, and which terminate, if the dose be large enough, in death.

3. These five principles are to all appearances identical in physiological action.

4. In small doses, not ending fatally, they produce—1st, cerebral excitement not succeeded by coma; and 2d, partial loss of sensibility.

5. In large doses they produce—1st, cerebral excitement; 2d, complete paralysis of sensibility; 3d, tetanic spasms and convulsions; and 4th, death.

6. They paralyze the entire posterior columns of the spinal cord, also the entire system of peripheral sensory nerves; but the anterior columns of the cord, and the peripheral motor nerves, are not paralyzed.

7. They frequently produce convulsions of a clonic character, but occasionally they cause tetanic spasms, which latter are sometimes so severe as to cause opisthotonos. They do this, not by excitation of the reflex function, but probably by acting directly on the cord itself.

8. They do not produce muscular paralysis.

9. They at first increase, then impede, and lastly stop the respirations.

10. They at first increase, and finally diminish, both the force and frequency of the heart's contractions.

11. They produce at first contraction, and afterwards dilatation, of the capillaries and small blood-vessels, with stasis of the blood, indicating first irritation, and subsequently paralysis, of the vaso-motor nerves.

12. They affect the temperature by, 1st, slightly lowering, and, 2d, increasing it.

13. They usually produce contraction of the pupil.

14. They produce an increase of the salivary secretion.

15. They induce a peculiar form of tenesmus, accompanied by a copious discharge of clear mucus from the bowels.

Dr. Bennett gives diagrams of the respiration, pulsation, and temperature, with elaborate tables of the results of his experiments, and details the manner of their performance. The animals used were frogs, mice, cats, and rabbits.

AFRICAN CUSTOMS (*Le Progrès Médical*, August 30, 1873).—M. Henry Blanc, at a recent meeting of the French Association for the Advancement of Science, *à propos* of a communication on the physiological theory

of love, gave an account of some curious customs which prevail among certain African races.

The Somalis, who inhabit the plains along the north-east coast of Africa, practise the following operation. During the month subsequent to the birth of a female child, the labia minora, which are greatly developed in this race, are removed, leaving a large raw surface on each side. These surfaces are brought into contact and retained there by a bandage surrounding the abdomen and thighs. A piece of feather is inserted into the lower portion of the wound, so as to prevent the union of its edges at that point, and to permit later of the free escape of the catamenia. Until the age of ten or twelve years—the nubile epoch—is reached, the children are entirely nude, and it is impossible to perceive any trace of the genital organs, the union being always so perfect that the surrounding skin seems to pass from one thigh to the other with its continuity unbroken. At the time of marriage the bride is carefully examined by the parents of the groom, and the ceremony only takes place if the skin covering the vaginal orifice is thoroughly intact.

If the husband be young and vigorous, his conjugal approaches are usually sufficient to remove this obstacle; if not, he contrives to make a way for himself with the help of a sharp stone. The females are cold and experience no excitation during copulation.

The Abyssinians, who live on the elevated plateaux of the same region, circumcise their children the eighth day after birth. With the girls this operation consists in the ablation of the clitoris, the labia being left intact. Their women are highly lascivious, and seem to live only for sensuality. Their language is rich in expressions denoting the pleasures of physical love, and prostitutes are held in high esteem. Among the Somalis also, those women who, through the negligence of their parents, have not undergone the usual operation, become prostitutes and show themselves possessed of strong sexual passions. M. Blanc concludes, therefore, that these differences cannot be considered as attributable to race or climate, but that the seat of the pleasure experienced by the females during copulation must be in the labia minora, and not in the clitoris.

APHASIA (*Dublin Journal of Medical Science*, October, 1873).—Mr. James Martin was called to see a boy, aged six years, who had been complaining of right-sided frontal pain for about five days, and who had awakened after a short nap, entirely unable to sleep. He was perfectly sensible; pupils natural; tongue furred; temperature 100°; pulse 120; respiration 32; kidneys acting well. Two powders of calomel and jalap were given, and a mixture containing iodide, bromide, and bicarbonate of potassium was ordered, and taken for a week, at the end of which time he was quite well. The attack was peculiar from the readiness with which it yielded to treatment, and from its seat being on the right side.

ABSCCESS OF THE LARYNX SIMULATING CROUP (*Edinburgh Medical Journal*, October, 1873).—Dr. William Stephenson details three cases of abscess of the connective tissue in immediate relation to the larynx. In the first it occurred in a child, æt. 4, convalescent from scarlatina, and was attended with labored and stridulous breathing, cyanosis, dysphagia, and inability to lie down. Secondary lung-complications ensued, and the child died, the abscess, situated on the outer side of the right thyroid cartilage, being only discovered after death.

In the second, the child, æt. 2, was just recovering from an attack of smallpox: the symptoms were similar to those of the preceding case, the difficulty of breathing had lasted for a week, the child sat in an erect position in bed, and a small swelling was observed immediately

below the thyroid cartilage. It was opened, and three or four drachms of pus were withdrawn, with immediate relief to respiration. The child sank and died some days afterwards, from the weak cachectic condition induced by the disease.

In the third case, a child, æt. 18 months, the trouble began with a glandular swelling under the lower jaw, which disappeared in the course of a fortnight, and was followed by a fulness in the lower part of the neck, a slight displacement of the larynx to the right, and difficult respiration. These symptoms increased, until at the end of the second week a small rounded soft swelling could be felt about the level of the isthmus of the thyroid and at the outer margin of the sterno-hyoid muscle. This was opened, four ounces of pus were discharged, the urgent symptoms were at once relieved, and the case progressed steadily to complete recovery.

Dr. Stephenson remarks that the diagnostic symptoms of this affection are almost precisely those of retro-pharyngeal abscess. The more gradual onset of the laryngeal trouble as compared with croup, the pain and difficulty of deglutition, the paroxysms of dyspnoea which ensue on that act, and, lastly, the preference for and comparative relief obtained in the erect position, are all points of great importance, and are all characteristic of both post-pharyngeal and laryngeal abscess. They are markedly distinct from the symptoms of intra-laryngeal affections.

The author, in conclusion, gives a short *résumé* of a paper by Dr. Parry, on "Abscess of the Larynx in Young Children," published in this journal on the 14th of June, 1873.

EPITHELIAL CANCER OF THE COLON (*The American Practitioner*, November, 1873).—Dr. S. Littell reports the case of a man, aged 49, who died from a malignant affection of the mucous membrane of the intestine, which had resulted in perforation of the colon, the formation of an abscess between the peritoneum and the integuments, and the establishment of an artificial anus in the back, a few inches to the left of the spinal column, and at a point nearly on a line with the upper margin of the kidney.

THUMB-SUCKING.—I have observed that a peculiar and rather common deformity of the chest is caused by the habit of sucking the thumb in infancy and early childhood. The weight of the arm on the thorax of the child during sleep produces depression of the ribs in the line occupied by the arm when the thumb is placed in the mouth. As this is a very important effect of "thumb-sucking" never hitherto pointed out, I think it desirable to place this note on record for the benefit of other observers.—*Dr. Horace Dobell, in British Medical Journal*.

ELEPHANTIASIS—TREATMENT BY LIGATURE.—Dr. Manduel publishes, in the *Lyon Médical*, a *résumé* of all the cases of elephantiasis treated by ligature of the main artery of the affected part. This operation, introduced by Carnochan, of New York, has been performed twenty-three times,—viz., on the femoral artery fifteen times, on the external iliac three times, on the anterior tibial twice, on the two carotids once, the brachial once, and in one case the artery is not mentioned. The successful attendant upon the operation has been thus tabulated: one died of pyæmia; in two cases, a negative result; four were attended by a speedy relapse; six were relieved, and eleven cured. The number recorded as cured is probably inexact, inasmuch as patients suffering from this disease are exceedingly prone to a relapse, and require to be kept under observation several years before the degree of success can be estimated.

Compression, which has the advantage of being com-

paratively harmless, has succeeded in some cases. Du-four has reported several. Vanzette, of Padua, records a case of a young girl in whom the disease attacked the right leg. Complete success followed compression, and at the time the case was reported, three years afterwards, the patient remained perfectly well. Quite recently Gosselin attempted the same treatment, but without favorable result.—*New York Medical Journal*, November, 1873.

THE BLOOD IN YELLOW FEVER (*New York Medical Journal*, November, 1873).—Dr. Joseph Jones has found by careful and laborious observations that the changes which occur in the blood in yellow fever consist chiefly in—

1. Such an alteration of the chemical and physical properties of the fibrin and albumen as leads to the transudation of the latter through the excretory structures of the kidneys.

2. Various degrees of alteration and diminution, and in some cases almost entire disappearance, of the fibrin. Here we have an important explanation of the cause of the hemorrhagic tendency in yellow fever.

3. Peculiar and irregular changes in the form and size of the colored blood-corpuscles.

4. Increase of the extractive matters of the blood.

5. Increase of the fatty matters of the blood.

6. Accumulation of bile in the blood, giving a golden color to the serum, and probably accounting for much of the nausea, vomiting, and cardiac depression, as well as for some of the cerebral symptoms.

7. Accumulation of the urinary constituents, especially the urea, phosphoric acid, sulphuric acid, chloride of sodium, and carbonate of ammonium. The blood is alkaline, and contains ammonia, resulting from the decomposition of the urea.

8. Rapid dissolution of the colored corpuscles after the blood is abstracted from the body, either during life or after death.

9. Rapid putrefaction of the blood after its withdrawal from the living body, or from the large vessels after death.

ACUTE IDIOPATHIC GLOSSITIS (*Irish Hospital Gazette*, November 1, 1873).—Mr. Frederick W. Warren reports a case of glossitis occurring in a temperate man, thirty years of age, and preceded by headache, constipation, and dysphagia. After three days of these premonitory symptoms, his tongue became immensely swollen, filling the mouth, causing great pain in swallowing, and rendering the speech inarticulate. The submaxillary glands and the whole hyoid region participated in the inflammation. Two parallel longitudinal incisions were made along the dorsum of the tongue, one on each side of the median line; four leeches were applied under the lower jaw, and a powder of calomel and jalap was given. The next day he was much better, but, as there were still some tenderness and swelling around the hyoid region, six leeches were applied to the seat of pain. A senna mixture was ordered, to relieve the constipation which persisted. In two days he was almost well, and in a week was discharged, cured.*

STRYCHNIA-POISONING (*Boston Medical and Surgical Journal*, November 6, 1873).—Dr. G. W. Copeland reports the case of a middle-aged man who took five grains of strychnia with suicidal intent. He was seen an hour and a half later, suffering from frequent convulsions, with great opisthotonos, and unable to swallow or articulate. Twenty grains of sulphate of zinc failed to produce emesis, and inhalations of chloroform were resorted to and continued for eleven hours with excellent effect. The convulsions grew less severe and less frequent, and finally ceased altogether, and the case terminated in recovery.

MISCELLANY.

TOOTH-PICKS.—The tooth-pick is certainly a hygienic instrument. Hence its consideration is within the province of a medical journal; wherefore we abstract the following remarks of S. Phillips Day from a recent number of the *Food Journal*, for the edification of our readers. Mr. Day may be master of anathema,—may be a Beau Brummel in society,—but he certainly is wrong in asserting that the proper use of the tooth-pick is injurious to the teeth:

"The other day that public censor, *Punch*, laid his hand rather heavily upon those 'Savages in Clubs' who, dead to all feelings of delicacy, adopt the revolting and brutal practice of picking their teeth with sharp instruments while at table, and even in the presence of ladies. One can scarcely conceive a habit more ungentelemanly, offensive, and abominable. . . .

"The tooth-pick, or pick-tooth, is derived, it appears, from the *stecco* of the Italians, and likewise formed the crude idea from which the two-pronged fork was drawn. The instrument was unknown in England before Queen Elizabeth's reign. A few of the early dramatists make reference to it. Thus, in Ben Jonson's 'Every Man Out of his Humor' (act iv., sc. i.), Fallace, the Citizen's wife, cries:

"O, sweet Fastidious! O, fine courtier! How cleanly he wipes his spoon at every spoonful of white meat he eats, and what a neat case of pick-tooths he carries about him still!"

"From this passage critics consider that although Fastidious carried a bundle of wooden skewers sharply pointed about his person, nevertheless he did not use them to pick his teeth, but simply for the purpose of conveying solid food to his mouth, just as the Chinese make use of chop-sticks for the like purpose; that is, to serve in lieu of a fork. Court gallants also employed spoons to eat white meat. The tooth-picks were carried in neat cases and were regarded as gewgaws. Hence they were used ostentatiously at meals, and on other occasions, by way of distraction. Thus, Overbury, in his 'Characters,' observes of an 'Affectate Traveller' that 'his tooth-pick is a main part of his behavior,' clearly intimating that the shocking habit of picking the teeth had not then been in vogue. This is further confirmed by Shakspeare, who in his play of 'King John' (act i., sc. i.) makes Philip the Bastard observe:

"He and his tooth-pick at my worship's mess;
And when my knightly stomach is sufficed,
Why then I suck my teeth."

"The pernicious practice of picking the teeth manifestly must have come into use during Dryden's time. In one passage of his plays we alight on the following curt allusion:

"These are not dishes for thy dainty tooth:
What! hast thou got an ulcer in thy mouth?
Why stand'st thou picking?"

"Sandys observes, 'If tooth-picks of the lentisc be wanting, of a quill then make a tooth-pick.' Lentisc, according to an old writer on husbandry, is a beautiful evergreen, and made the best tooth-picks.

"Some persons in America are particularly addicted to the foul practice of using tooth-picks. In fact, not satisfied with the vigorous employment of such weapons during meals, they are said to carry them in their mouths out of the dining-room, and to keep digging at their teeth or else twirling them between their lips for an indefinite period. This is an amusement equal to 'whittling;' and 'a certain Yankee,' as has been incisively observed, 'can "whittle" a tooth-pick out of a pine log.'

"Nothing can well be more revolting to sensitive, cleanly persons than the habit of picking the teeth, either at meals or afterwards. The material of which the nasty instrument of torture is made, whether of wood or quill, does not render the practice less reprehensible. I lately observed in a shop-window in Holborn a box of pretty-looking 'diaphanous' tooth-picks imported from France; and it sorely grieved me to think that so much ornamentation should be bestowed upon such injurious articles. The use of tooth-picks should not be tolerated in civilized society, especially in what is termed 'good society.' Negroes do not need such things; then why should the white man? Savages can get on very well without such skewers; then why should Christians patronize them? Besides, they are highly injurious to the human teeth, creating apertures between them, destroying the delicate enamel which protects them, thus inducing premature decay. Therefore, both on the grounds of decency and health, the tooth-pick should be universally eschewed."

DEAF AND DUMB.—Dasent estimates that in Europe alone there are 200,000 afflicted in this way. In mountainous regions, as in Switzerland and Savoy, the proportion is very great. In the Berne Canton there is one to every 195 inhabitants; in Scotland, one to 196. In Great Britain, however, the proportion is only one in 1660; in Ireland, one in 1380. At the census in 1851, there were 12,553 deaf and dumb,—6884 male, 5669 female. They have increased in number during the last twenty years, the former still heading the list.—*British Medical Journal*.

At a meeting of the Anatomical Class of the Jefferson Medical College, Robert M. Hays was called to the Chair, and E. R. Lewis appointed Secretary.

The following preamble and resolution were unanimously adopted:

Whereas, the Anatomical Class of Dr. William H. Pancoast, and the students of the college generally, have heard of the great and irreparable loss which he has just sustained in the death of his beloved wife, who was personally known to many of us, and highly esteemed by all: therefore,

Resolved, That they hereby tender to him the expression of deep sorrow which they feel on this sad occasion. They wish also to assure their valued teacher, who has so thoroughly won the friendship and affection of his class, that they sympathize sincerely with him in his bereavement, and offer to him their sincere condolence.

JOHN V. SHORMAKER,	} Committee.
A. P. BRUBAKER,	
C. E. SAYLES,	
ROBERT MCCONAUGHY,	
D. R. MILLER.	

THE next Conversational Meeting of the Philadelphia County Medical Society will be held Wednesday, December 10, 1873, at 8 o'clock P.M., at the Hall of the College of Physicians. All regular practitioners of medicine in the city are cordially invited to attend these meetings. The subject

before the next meeting will be "The Use of Alcohol Medicinally and Socially." The introductory paper will be read by Dr. George Kert.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 25, 1873, TO DECEMBER 1, 1873, INCLUSIVE.

WOLVERTON, W. D., ASSISTANT-SURGEON.—Assigned to duty at Nashville, Tenn. S. O. 202, Department of the South, November 21, 1873.

GREENLEAF, C. R., ASSISTANT-SURGEON.—Assigned to duty at Huntsville, Ala. S. O. 202, c. s., Department of the South.

CALDWELL, D. G., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Wolverton, to comply with War Department orders in his case. S. O. 202, c. s., Department of the South.

TAYLOR, M. K., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Greenleaf, to comply with War Department orders in his case. S. O. 202, c. s., Department of the South.

KING, W. H., ASSISTANT-SURGEON.—Granted leave of absence for thirty days, with permission to leave limits of Department and apply at Division Headquarters for an extension of ten days. S. O. 204, Department of the South, November 26, 1873.

SATURDAY, DECEMBER 13, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE MEDICAL TREATMENT OF GRAVEL AND CALCULI.

BY JAMES TYSON, M.D.,

Clinical Lecturer on Microscopy, Urinary Chemistry, and Renal Diseases in the University of Pennsylvania.

Delivered September 26, 1873.

IN a previous lecture I asked your attention to the formation of urinary calculi, and the method for determining their composition,—means so simple and easy of application that they should be familiar to every practitioner. To-day we will discuss the treatment of the condition incident to their presence and the tendency to their formation. None of you who have witnessed a case of nephritic colic need be impressed with the importance of being able to relieve the painful symptoms of this condition, or, still better, if possible, to prevent their occurrence.

The treatment naturally resolves itself into the *preventive*, the *solvent*, and that required during a *paroxysm* of nephritic colic. A hasty conclusion would seem to require that the latter two should be identical; but, when we come to consider the efficiency of the solvent treatment, we will soon discover that it is far too slow in its action to be relied upon when pain so severe as that caused by impaction of a stone is to be relieved.

I. Suppose, then, you are called upon to treat a patient in the agonies of nephritic colic, so called. Under these circumstances a small stone is supposed to have left the pelvis of the kidney and to be working its way through the long but narrow ureter, whose diameter is not greater than that of an ordinary knitting-needle, if as great. The evidence of such an attack is discovered in a degree of pain which is seldom surpassed in severity, and which, starting in the lumbar region, extends thence along the line of the corresponding ureter and groin to the testicle, which is often retracted. It is scarcely possible to mistake the import of such pain; and very likely the patient, from his experience in one or more previous attacks, will himself have made the diagnosis.

At this stage the composition of the stone is not of material importance. To relieve the pain is the urgent demand. Happily, means are at our disposal promptly to do this. A hypodermic injection of the one-sixth of a grain of sulphate of morphia, followed by hot poultices constantly kept up, will generally so far influence the pain as to give you at least a breathing-spell in which to prepare yourselves for further action. Suppositories containing one-half grain of extract of opium or a grain of powdered opium, with one-half grain of extract of belladonna, should be ordered, with directions that one shall be introduced into the rectum every three hours. A

more frequent use will scarcely be of further service, since not more than the quantity named is likely to be absorbed in this time. A hot bath may also be suggested in case relief is not obtained, and the hypodermic injection may be repeated, if necessary, at the next visit.

A specimen of urine should be obtained, if possible, before the second visit, and examined microscopically. In a certain number of cases no information whatever will be derived from it. In others, again, you will promptly detect crystals of uric acid, sometimes large enough to be seen with the naked eye, in the shape of the so-called "red-pepper" grains; in others the microscope will detect octahedra and dumb-bells of the oxalate of lime. In the former instance you have a uric acid calculus to deal with; in the latter probably a small stone of oxalate of lime, though not necessarily, since a deposit of crystals of oxalate of lime sometimes attends uric acid concretion; but the probabilities of the oxalate composition will be greatly increased if the crystals, whether octahedra or dumb-bells, tend to aggregate themselves, thus forming *microscopic calculi*. Whenever this has been the case, and I have subsequently obtained the stone for analysis, I have invariably found it to be composed of oxalate of lime. Phosphatic calculi are rarely the occasion of nephritic colic, since they are never found as primary stones in the kidney, nor indeed in the bladder; but are subsequently added to previous nuclei of whatever composition, in consequence of an alkaline reaction induced either in the whole mass of the urine or that immediately around the calculus, as the result of which the triple phosphates and phosphate of lime are deposited in consecutive layers.

Should such examination of the urine lead to a conclusion that the offending stone is uric acid, large doses of citrate of potash may be administered in connection with the anodyne treatment, partly in application of the principle to be presently explained in connection with the solvent treatment, and partly with the hope that by flushing the kidney with water the concretion may be pushed onward towards the bladder. If the calculus be oxalate of lime, such treatment can only be justified by the latter motive, since to hope for its solution is futile.

Should the patient become nauseated in the course of the above treatment, you may assure him that such a result is really desirable, since the increased pain is often due to a spasm of the muscular coat of the ureter, as the result of which the stone is more closely grasped, while the condition of relaxation due to the nausea may aid in interrupting the spasm, and thus relieve the pain.

Supposing the attack terminated, the stone has either reached the bladder, or, having established a temporary tolerance in some part of the ureter, remains quiescent for a time. In the former case it will probably be passed by the urethra, and, for the discovery of it, careful examination should be made; while in the latter it will inevitably excite another attack at some period more or less near.

II. It is with a view to dislodging such, as well as aiding in the escape of other stones which may be resting in the pelvis of the kidney, that the *solvent* treatment is used. By means of carefully conducted experiments by Dr. Roberts, of Manchester, England, author of the very useful practical book on "Urinary and Renal Diseases," we have arrived at quite accurate knowledge of our powers in this direction.

In the first place, however, let us recall the composition of renal calculi. For practical purposes it may be stated that three-fifths of all stones in the bladder have been found to be composed of uric acid or its compounds, two-fifths of phosphatic combinations, and three or four per cent. of oxalate of lime. But I have already said that phosphatic stones of small size rarely, if ever, exist in the pelvis of the kidney. It is only when calculi have reached considerable size, so that by partial occlusion of the ureter the urine has become backed towards the kidney, and in consequence of its accumulation has acquired, through decomposition, a change in its reaction, that the phosphatic laminæ are deposited, and at this stage curative medical treatment is totally out of the question. Indeed, it has been proven that the nuclei of almost all calculi which have commenced their formation in the pelvis of the kidney are composed of uric acid or oxalate of lime; and in a large number of calculi composed of uric acid there is found to be an oxalate of lime nucleus.

The solvent treatment, therefore, resolves itself into attempts to dissolve calculi of oxalate of lime or uric acid and its compounds. The general method of Dr. Roberts was to allow alkaline solutions to flow over stones soluble in alkalies,—that is, uric acid, urates, and cystine (a very rare concretion),—at a rate simulating that at which urine is supposed to trickle down from the kidney through the ureter; while acid solutions were caused to flow over those found soluble in acids, *i.e.*, oxalates and phosphates. The result of these observations proved that it is not impossible to produce some effect upon uric acid; that all attempts to dissolve oxalate of lime or mulberry calculus are futile; and that, although phosphatic concretions are susceptible to the action of acid solutions, the practical impossibility of producing through the system a sufficient degree of acidity of urine restricts the application of the principle to injecting the bladder with such solutions, with a view to acting upon phosphatic stones in that situation.

From this we learn that there is only reasonable possibility of acting upon uric acid and cystine with a view to diminishing their size by solution. The experiments of Dr. Roberts have also informed us what alkaline salts are most useful for this purpose. In the first place, he has shown that the potash salts are more efficient than the soda salts, and, secondly, that of these the carbonates are the most active. But it is well known that the citrates, acetates, and tartrates become converted into carbonates by the time they reach the kidney, or at least are eliminated as such; and in these we have preparations very much more agreeable, as well as more soluble

and better borne by the stomach, than the carbonates themselves. They become, therefore, the most suitable remedies to administer; and perhaps the citrate is to be preferred,—especially if no purgative action be required; but the acetate may be interchangeably used. Of these salts of the vegetable acids forty to fifty grains may be given every three hours, freely diluted, say in three to four ounces of water, with lemon or other vegetable syrup added, if desired, to flavor: about six drachms of the salt should be taken by an adult in twenty-four hours. Of course liquor potassæ and the bicarbonate of potash come under the same category; so also the lithia salts; but there is considerable difference of opinion as to the efficiency of the latter, some vaunting them very highly, while others declare them inactive on account of their sparing solubility, and I have not had sufficient experience with them to be justified in giving an opinion.

Some interesting facts, with which you should be familiar, were developed by Dr. Roberts as to the strength of the solvent solutions employed, since upon them is based the appropriate dose of the remedies. Thus, it was found that a strength of less than forty to sixty grains of the bicarbonate to the imperial pint was very much more feeble, while, on the other hand, solutions containing more than sixty grains to the pint exhibited also a diminution in solvent power, which was finally arrested by the formation of a white crust of alkaline *bi-urate* on the surface of the calculus. With a solution of eighty grains to the pint this bi-urate crust was loose and easily detached, like a layer of whitewash; but with a solution of one hundred and twenty grains to the pint it was tenaciously adherent, and very little dissolution took place with carbonate of potash, and none at all with carbonate of soda. With solutions of one hundred and sixty and two hundred and forty grains to the pint, there was no loss of weight with potash or soda; the fragments of stone became invested with a thin tough coating of bi-urate, resembling white paint, which put a stop to all solvent action.* The quantities of the vegetable salts above mentioned, and in the manner described, have been found by Dr. Roberts to produce the degree of alkalescence required; and he found further that when urine alkalized by the internal administration of these salts was passed over the surface of uric acid calculi at blood heat, the calculi underwent solution at the *mean rate of twelve and a half grains in twenty-four hours*. Such an exhibit at least merits a trial, and, as far as my experience goes, the trial has been justified by the results.

The treatment should be kept up for a considerable length of time, but should be discontinued when an ammoniacal state of the urine is developed, since under this condition solution ceases, while on the other hand a deposition of mixed phosphates (triple phosphate of ammonia and magnesia and amorphous phosphate of lime) takes place on the surface of the calculus, and it of course becomes larger. The simple presence of amorphous phosphates,

* Roberts's Urinary and Renal Diseases, p. 240, first American edition. Philadelphia, 1866.

however, which are often observed, particularly after a meal, need be no contra-indication, since they do not interfere with solution and are not disposed to concretion. It is the ammoniacal state which is to be avoided. An interruption of the treatment should be enjoined at such times until the urine again becomes acid.

Such is the solvent treatment of uric acid gravel; and, if it be clearly borne in mind what alone is claimed for it, a power of partial solution or diminution in size of small calculi, so that they may more readily pass through channels ordinarily much too contracted for them, and not the destruction of large stones already in the bladder, there need be no disappointment in its results. A stone in the bladder of considerable size should be turned over to the surgeon, who with his knife or lithotrite will make quick work of it.

You may perhaps wonder why I have said nothing about Vichy or other alkaline waters, which have not only had so much reputation in dissolving uric acid stone, but have also been used with such reckless indiscriminatio in all calculous disease, without regard to composition or indication. I have purposely made them secondary, because I believe them to be very much less efficient than the alkaline citrates and acetates of potash, while they are more expensive and difficult of access. And in this I am only following the precept of one whose great experience in these maladies entitles him beyond all others to our respect,—Sir Henry Thompson, who twenty years ago declared the "citrate and carbonates of potash are more potent and certain than Vichy water," and who says, so recently as 1873, "I have never at any time prescribed Vichy water for any urinary affection* on the ground of its inferiority to the potash solutions." I think the citrate may be fairly said to be the salt which of all others offers the best chance of success; and this by common consent of all who have examined the subject." Compared with such authority as this, confirmed by the carefully conducted experiments of Dr. Roberts, my own testimony to the same end is of little value, except that it adds one more to the list of those "who have examined the subject." I might say of the Vichy water that the alkali which it contains is the carbonate of soda, and not of potash, and of the former salt there are forty-seven grains to the English pint.

III. But if much may be expected from the solvent treatment of gravel, more may be expected from the *preventive* plan. Here also, for the reasons already stated, it becomes practically the preventive treatment of *uric* acid concretion and its congeners. And although it is the case that oxalate of lime calculi are quite insoluble in the solutions efficient in dissolving uric acid, and indeed in the system in any solutions, it happens that the circumstances attending their production are almost identical with those attending the formation of uric acid, and that the preventive treatment of the

latter becomes therefore the preventive treatment of oxalate of lime.

What, then, are the indications for the use of this treatment, by which we hope to prevent the formation of stone in the urinary passages? It is well known that urates, uric acid, and oxalate of lime crystals are occasionally found in the urine of individuals who are perfectly healthy. And you will many times be called upon to dispel the illusion based upon the appearance of "sediment" in the urine of a patient who is rendered unnecessarily wretched by that fact, and who is really in perfect health.

These deposits are apt to appear in urine, sometimes in considerable quantity, not only after an attack of indigestion, but also from defective assimilation even without symptoms of indigestion, and by whatever cause induced, whether from gross disregard of the proprieties of eating, or the use of a single glass of wine to which one has not been accustomed. And oxalate of lime crystals are almost always found in the urine after a meal of vegetables containing oxalic acid, as of sorrel, tomatoes, or rhubarb. I have often told you that when I wish to obtain examples of the octahedra of oxalate of lime, for examination with the microscope, I always secure a good crop in my own urine by eating a full meal of the rhubarb or pie-plant, if it be in season; in a few hours after which, my urine is loaded with beautiful crystals of large size. I also know a medical gentleman who is unable to eat tomatoes, because of the crystals of oxalate of lime which appear in his urine and give him pain in their descent to the bladder.

How, then, are you to determine the presence of the so-called "uric acid diathesis"? In the first place, by the persistence of the deposit, which is usually pinkish in hue, or gives to the urine a cloudy appearance which is dissipated by heat. And here I must again caution you against a deposit which always takes place when urine is cooled much below the temperature of the blood. The urates in health are usually present in the urine in such quantity that they are dissolved at the temperature of the body,—that of the urine when it is passed,—or even at a temperature somewhat lower. In cold weather, therefore, when the urine becomes cooled much below that point, a deposit inevitably takes place, which is usually found made up of the amorphous mixed urates of potash, soda, lime, and magnesia, and is physiological.

If, however, having observed the precautions suggested by the above facts, the deposit persists day after day, and you find upon inquiry, as you will be very likely to, that the patient's father or grandfather had attacks of "gravel" (for the affection is very constantly hereditary), you may conclude that you have a case of uric acid gravel. Or if the patient or his ancestors have had gout, you may be equally confident; because this is also well determined, that uric acid gravel and gout are identical in their causation. For, in addition to the fact that the gouty deposits in the joints are made up of mixed urates generally crystallized in acicular form, we have numerous cases in which an attack of

* The Preventive Treatment of Calculous Disease, p. 58, Lindsay & Blakiston, Philadelphia, 1873.

gout alternates with one of uric acid, or one member of a family has gout and another uric acid gravel. Indeed, gouty patients almost always have deposits of urates and uric acid in their urine. Finally, I need only allude to the inference you may draw if the patient has already suffered an attack of nephritic colic.

Supposing the presence of such a condition determined, how will you manage it in order to prevent the final great evils, renal calculi or stone in the bladder? Here, as elsewhere, the foundation of a correct treatment must be a knowledge of its pathology. And what is the pathology of uric acid, and I may say also of oxalate of lime deposits? With one universal accord the persistent presence of these deposits in the urine is admitted to be indicative of deficient assimilation. From some cause or other, food which should be worked up into completely soluble substances stops short at principles which are most insoluble, and which, therefore, are deposited, in the crystalline shape alluded to, in the tubules of the kidney and pelvis of the organ, where they act as foreign bodies, causing irritation and pain, and in their aggregation form the calculi the transit of which to the kidney causes so much suffering. Attending this condition is often found a so-called torpor of the liver and bowels,—that is, a condition which, whatever its true nature, is attended with deficient excretion into the alimentary canal.

Under these circumstances the kidney is already overworked in its attempt to remove from the blood these insoluble and irritating substances, and the indication is to relieve it by throwing the work, or a part of it, on some other organ. It is not sufficient to administer Vichy water or other alkaline substances, which by dissolving the uric acid and urates simply hide the enemy without preventing its presence. Such a course is aptly compared by Sir Henry Thompson to that of the fabled ostrich which is said to bury its head in the sand when pursued, and believes itself secure because it no longer sees its enemy. There may be, it is true, palliation of symptoms by such treatment, and the patient may be for the time relieved as well as comforted by the fact that he no longer *sees* the deposits, but they will often return when the remedies are discontinued.

This is, of course, admitting a purely *chemical* action of alkalis in promoting the solution of uric acid; but it is too sweeping an assertion with regard to the valuable citrates, tartrates, and acetates previously alluded to, which have been shown by Drs. D. Campbell Black, Basham, and Geo. Harley to have something more than an action of this kind, and to possess also, when administered, an important *physiological* action through which the oxidation processes of the economy are much increased, so as to transform the slightly soluble uric acid into the highly soluble urea,—apparently through an increased activity of all the digestive functions. Nor is this effect overlooked by Thompson, who alludes to it in claiming the superior efficiency of the citrates and tartrates over Vichy and similar carbonated waters.

If, however, it is possible to divert some of the work of the kidney to another channel, and thus relieve an organ already overworked, it is much better at least to superadd and sometimes, perhaps, to substitute such treatment. This may be accomplished by acting upon the liver and bowels,—organs which in their combined action are quite as important excretors as the kidney. Few who have had experience in these cases have not seen the advantage of a mercurial purge at night, followed by a saline the following morning. The constant use of these means, however, would be impossible, for evident reasons, and others must be sought, in application of the same principle of complementary elimination. Such means are afforded in the natural *saline* purgative waters, for the general introduction of which we are also largely indebted to Sir Henry Thompson. These have for their chief ingredients sulphate of soda and sulphate of magnesia, and are represented by the Püllna, Friedrichshalle, Marienbad, Carlsbad, and Franzenbad Springs in Germany. The Püllna waters contain about one hundred and fifty-four grains of sulphate of soda and one hundred and sixteen grains of sulphate of magnesia to the English pint; those of Friedrichshalle, fifty-eight grains and forty-nine grains, respectively; those of Marienbad, forty-eight grains of sulphate of soda, none of magnesia, nine grains of *carbonate* of soda, and a little iron. The Carlsbad contain twenty-five grains of sulphate of soda, no magnesia, and thirteen grains of carbonate of soda; the Franzenbad, thirty grains of sulphate of soda, no magnesia, six grains of carbonate of soda, and a little iron. In contrast with these, Vichy contains but three grains of sulphate of soda, no magnesia, forty-seven grains of carbonate of soda, and a little iron, to the pint; and Vals, none of the former two, but sixty-five grains of carbonate of soda, with a little iron. The latter are, therefore, as already stated, simply strong solutions of carbonate of soda.

Of these waters, that to which Sir Henry Thompson gives the preference, and that upon which my own experience has been based, is the Friedrichshalle, the Püllna having been found to purge too freely and to produce griping. Of the Friedrichshalle about eight ounces or an ordinary tumblerful may be given every morning about an hour before breakfast. This is usually followed after breakfast by one or two full copious stools, produced by about twenty-five grains of sulphate of soda and twenty of sulphate of magnesia,—quantities which if dispensed from the shops or even by evaporating the proper amount of the natural water would probably have no effect whatever, though the latter would still be more efficient than the salts as ordinarily obtained. Thus there will be seen to be some peculiar efficacy in the natural waters, the cause of which is not precisely known. This treatment should be kept up for three weeks to a month, and after a short intermission be returned to. In continuing the treatment, there will be found this important advantage, that, instead of having to increase the quantity each day, it may be diminished, while the effect will still continue, so that by a gradual reduction, at the end of three weeks, four ounces will

have as much effect as eight at the outset. It is occasionally of advantage to precede the treatment by a small dose of blue pill,—three to four grains; this, if digestion be deranged, the appetite bad, and the tongue foul. Sir Henry Thompson also recommends the use of five ounces of hot water in connection with the eight or reduced amount of the Friedrichshalle; but I have found patients complain of discomfort evidently due to a distention of the stomach when this dose is administered. When it can be borne, additional effect may reasonably be expected from the dilution as well as the increased temperature, since in both these respects it is made to approach the character of the water at the spring, which is hot and less concentrated than that which is exported. The increase in temperature may also be obtained by placing the glass of water in a second vessel containing hot water.

You may wish to know precisely the plan of the eminent English surgeon. It is to administer the Friedrichshalle as above directed for one, two, or three weeks, according to the nature of the case and results, and then to combine with three or four ounces of it five or six of the Carlsbad, which you will recollect contains twenty-five grains of the sulphate of soda and thirteen of the carbonate to the pint; it is therefore more alkaline. To this combination he adds three or four ounces of hot water. After giving this for two or three weeks, six, seven, or eight ounces of hot Carlsbad are given alone for another fortnight. This course may be repeated once in three or four months, if necessary, while in the mean time, as an occasional aperient and corrector of digestion, he knows nothing at all equal to Friedrichshalle, leaving the patient, as a rule, less constipated than he was before. With a very much less experience, of course, but having examined the subject with considerable care, and having lost no opportunity of testing the plan, it has seemed to me we can do much more for these cases than formerly.

Should the Friedrichshalle prove insufficient in some cases, the Püllna may be substituted as a more powerful water, containing, as it does, nearly two and one-half drachms of sulphate of soda and nearly two drachms of sulphate of magnesia to the pint.

These waters, including Püllna, Friedrichshalle, and Carlsbad, are now easily obtained in this country, being largely imported by a Philadelphia firm. I must say, however, that the various salts of these waters advertised for sale as the "Carlsbad salt," "Püllna salt," etc., are no substitute for the natural waters, having very little more virtue than the same quantity of salts obtained from other sources.

The expense of obtaining these waters in this country will doubtless be an obstacle to your ordering them for some patients. I have therefore taken some trouble to find out which of the numerous American spring waters correspond or approach them in composition. Most prominent among these I find the waters of Crab Orchard Springs, located at Crab Orchard, Lincoln County, Kentucky. These waters contain 7 grains of sulphate of soda, and 25.6 grains of sulphate of magnesia, to the pint. From these are derived by evaporation the cele-

brated Crab Orchard salts, whose superiority over the ordinary Epsom salts is well known. These contain 63.19 parts of sulphate of magnesia, 4.20 parts of sulphate of soda, with smaller quantities of sulphate of potash and lime, in 100. Besides being less irritating than Epsom salts, they possess the advantage claimed for Friedrichshalle of not requiring the daily quantity necessary for an effect (at first a drachm freely diluted) to be increased. The Estill Springs, located in Estill County, Kentucky, furnish thirty-three grains of sulphate of magnesia to the pint; but no sulphate of soda is named in the analysis of Dr. Robert Peter, which I find in Walton's Treatise on the Mineral Springs of the United States and Canada.

The well-known Bedford Spring waters at Bedford, Pennsylvania, also belong to this class, though containing but ten grains of sulphate of magnesia to the pint. They are also chalybeate, and are said to resemble the Franzenbad waters of Bohemia, to which we have referred; but the latter contain thirty grains of sulphate of soda to the pint, while the Bedford contain but ten grains of sulphate of magnesia. The beautiful location of Bedford, in connection with the undoubted medicinal value of its waters, renders it a very popular summer resort. I may add that "gravel" and "calculus" are among the ills for which Bedford water has long claimed efficiency. The numerous Saratoga springs contain almost none of these valuable ingredients, but pre-eminently chlorides and carbonates. Thus much of information, and something more, you should have of American spring waters, in order that you may intelligently advise those who consult you with regard to them. It is not unlikely that the skepticism with which American physicians have hitherto regarded the medicinal effects of spring waters has been, in part at least, due to our ignorance of their actual qualities, and that we are, therefore, in a measure responsible for their having largely fallen into the hands of empirics. Much valuable information may be found in the volume above alluded to, and one or two others recently issued from the American press.

There is one more point in connection with the preventive treatment of calculous diseases to which I must call your attention, and that is diet. I have already alluded to the effect of certain vegetables, as the rhubarb or pie-plant, tomato, and sorrel, in promptly producing crystalline deposits of oxalate of lime. By persons, therefore, inclined to oxalate of lime concretions, these should be avoided. There is also reason to believe that potable waters charged with the salts of lime increase the tendency to the formation of oxalate of lime calculi. To the same end, fatty matters, saccharine substances, and those containing sugar or readily converted into it, as sweet fruits, together with alcoholic drinks, should be omitted by those subject to uric acid deposits; the use of these matters increasing the work of the liver, and, with it, the vicarious action of the kidneys. While the use of a purely nitrogenous diet is, for the same reason, to be avoided, and the free use of vegetables, regarding the exceptions named, to be recommended, total abstinence from animal food is not

necessary or desirable. Nor need tea and coffee be interdicted, these substances having been shown to diminish the formation of uric acid and increase that of urea, acting, therefore, like the citrates, acetates, and tartrates. Quinine, digitalis, atropine, and cod-liver oil are placed in the same category,—diminishing the formation of uric acid and urea as well,—and may be used in connection with the previous treatment as the patient's condition or special circumstances may require.

ORIGINAL COMMUNICATIONS.

MALIGNANT DISEASE OF THE EAR, WITH PARALYSIS OF SOME OF THE CRANIAL NERVES.

BY GEORGE C. HARLAN, M.D.,

Ophthalmic and Aural Surgeon to the Children's Hospital.

E. C., three years of age, was brought to the dispensary of the Children's Hospital to be treated for a disease of the left ear. She had had scarlet fever a year before, and had not been in good health since. About three months before, she had become restless, slept badly, and seemed in pain, and within two months attention was for the first time called to the ear by a slight bloody discharge. Soon after this it was noticed that she had pain in swallowing, that the parts about the ear were swollen, and that the face was drawn to the right side when the child cried. Her appetite failed, and she became very feeble.

At the time of examination, August 4, there was a slight amount of thick purulent discharge in the meatus, on removing which, a large, firm, rounded polypus, the size of a pea, or larger, was found blocking up the meatus. There was a fluctuating swelling beneath and behind the auricle. When the polypus was removed, by means of Wilde's snare and the rectangular forceps, there was a considerable discharge of sanious pus, increased by pressure on the external swelling. A free incision of the external swelling gave exit to a copious discharge of offensive pus. No dead bone could be detected by the probe. The left side of the face was swollen and puffy, and the mouth much distorted to the right side in crying. The left eye was never closed, even in sleep. The conjunctiva was free from congestion, the pupil movable, and the cornea clear and bright. There had been a convergent squint of the right eye of long standing, but the mother said this was increased, and the left eye was also inverted. The left half of the tongue was much swollen and rough, in strong contrast to the right, which was normal.

August 8.—The polypus had grown again nearly to its former size, and was again removed by forceps without pain and with only a few drops of blood.

August 20.—The polypus had grown again to its former size. The incision behind the ear, which had been kept open with difficulty by tents, was now gaping, and a fungous growth appearing in it.

On August 29 the polypus had become strangulated and sloughed off, and the external tumor had grown to the size of a walnut. There was a free discharge of healthy pus by the side of the tumor.

The upper lid was now immovable, and nearly closed, the conjunctiva injected, and the cornea dimmed.

September 1.—The tumor had increased to the size of a hen's egg. It was lobulated and had a bright-red granular surface.

The upper lid was now quite closed; the conjunctiva

was much congested, and the whole cornea was hazy and its lower fourth infiltrated. The convergent squint had nearly disappeared. There was a free sanious discharge from the *right* nostril.

September 17.—There was a penetrating ulcer of the cornea with protrusion of the iris: as the patient's mother aptly expressed it, "the eye seemed to be melting away."

September 21.—The child was breathing with difficulty through the mouth and the right nostril, which was much dilated and expanding and contracting laboriously.

She died September 25, apparently of exhaustion. No post-mortem examination was permitted beyond the removal of the tumor. The bone at its base was found roughened and eroded.

The tumor was exhibited to the Pathological Society and pronounced by the Committee on Morbid Growths to be a round-celled sarcoma.

The chief points of interest in this case are afforded by the nerves involved in the disease.

Such extensive destruction of the walls of the tympanum could not well occur without affecting the portio dura in its passage through the aqueduct of Fallopius, and causing the complete facial paralysis which appeared among the earliest symptoms. The difficulty of breathing was evidently much increased by the loss of the respiratory action of the left nostril, and the excessive action of the right nostril was painfully apparent. It is known that section of both facial nerves in the horse will cause the animal's death from suffocation; and we may well suppose that so young a child would find greater difficulty than an adult in breathing through the mouth.

Paralysis of the sixth nerve increased the convergent strabismus, which was corrected and the ball rendered immovable when the disease extended to the third.

The levator palpebræ was at the same time involved, and the eye, which had been held widely open in consequence of paralysis of the orbicularis, was now closed by falling of the lid.

The inflammation of the conjunctiva and cornea which appeared at this time presented a typical case of neuro-paralytic ophthalmia, without doubt due to paralysis of the fifth, or of its ophthalmic branch, and a point of special interest is the fact that the destructive inflammation of the cornea did not commence until after the ptosis had completely closed the eye. This excludes the theory that the affection of the cornea in such cases is always due to the mechanical injury of external irritants of whose presence the eye has been rendered unconscious. Though much weakened of late, and by some now abandoned, this theory was at one time generally admitted to be well established. Soelberg Wells speaks of it as "uncontrovertibly proved by the experiments of Snellen and others."

The free muco-sanious discharge from the right nostril was a singular phenomenon, no other symptom of nerve-lesion having appeared on that side. An increased discharge from the nostril of the affected side has been noted by experimental physiologists after section of the fifth nerve, but there was no excessive secretion from the left nostril in this case.

A similar increase of nasal secretion on the side opposite to the injury is noted in a case of injury to the sympathetic nerve in the neck, reported by J. F. Payne (St. Thomas's Hospital Reports, vol. iii., new series).

There is a bare possibility that the hypertrophy of the left side of the tongue might have been congenital. But this does not seem likely, as it was so marked that it scarcely could have escaped notice, and the child was otherwise perfectly symmetrical. Though the chorda tympani was necessarily, and the gustatory probably, involved, I am not aware that either paralysis or irritation of either of these nerves has been known to produce such a result.

The nervousness and peevishness of the little sufferer, who cried whenever I came near her, rendered it impossible to test the smell or taste, or even the general sensation.

NOTES ON SKIN-GRAFTING IN INDOLENT ULCER; ALSO, ON RETAINING DRESSINGS IN ORCHITIS.

BY ALFRED C. GIRARD, M.D.,

Assistant-Surgeon, U.S.A.

CORPORAL —, 1st Artillery, reported sick with an indolent ulcer on the inner surface of the right leg, close to the tibia, and four inches below the knee. Had been in hospital the preceding year with the same complaint on the same spot. Apparently no constitutional disease; slight varicosity and signs of stagnation in the veins of the ankle. The ulcer was almost circular, had a diameter of three inches, and presented the usual appearance, with particularly hard, elevated, and ragged edges. Cauterization, poulticing, and strapping were tried for two weeks, without the slightest change being produced, when I determined on trying skin-grafting, which I had once found quite useful in the treatment of a large syphilitic ulcer involving the whole of the ankle. I excised two small pieces of skin of the size of a millet-seed from the abdomen, and laid them on some of the irregular granulations in the centre of the ulcer. In six hours, as if by magic, the bottom of the sore appeared raised, the edges lost their callous appearance, and the next morning—twenty-four hours after application of the grafts—cicatrical tissue commenced bridging over the space between them and the edges. In one place, however, where the edge was undermined and ragged, farthest from the grafts, no change had taken place; and I applied a third graft in its vicinity with equally satisfactory results. In seven days the ulcer was entirely cicatrized without other treatment.

I may as well mention here an appliance which has given me great satisfaction in the treatment of gonorrhœal orchitis. Every physician knows the annoyance caused by the usual strapping with adhesive plaster in this complaint: the dressing is either too tight, and consequently very painful to the patient, or else loose, and then useless. In either case it has to be removed frequently, causing

much labor to the dresser and pain to the patient. I therefore tried the "*elastic bands*" which are furnished the army for stationery, imprisoning at first the testicle with the smallest size, and selecting for the compression such sizes as could be well borne by the patient. I thereby secured *constant, easy, and painless* compression; the dressings could readily be changed for any purpose, and admitted of other local treatment if found desirable. This mode of treatment has proved very successful.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS, M.D.

Reported by JOHN B. ROBERTS.

AMPUTATION OF THE LEG ON ACCOUNT OF CARIES OF THE ANKLE.

THIS boy was struck upon the ankle with a stone, nine years ago; which injury, acting as an exciting cause, has been followed, in a child of the scrofulous diathesis, by caries of the tarsal bones, as is proved by the probe introduced into any of these sinuses leading to the joint.

The disease is so extensive that excision of the ankle-joint and amputation at the inferior third of the leg are the only procedures worthy of consideration. In the main, amputation is the more expedient in these cases, since it can be done with very little risk to life, and is less likely to be followed by erysipelas and violent inflammation than excision; which latter operation at best gives a shortened limb and an ankylosed joint. Nevertheless, as it is doubtful how much of the tarsus is involved in this instance, I shall endeavor to resect, hoping that the disease is limited to the articular surfaces of the joint. If, however, it is found impossible to remove all the carious bone by this means, it will then, as an attempt to preserve the foot has been made, be proper to amputate through the leg.

A curvilinear incision having been made over the outer side of the foot, the tendons of the peroneal muscles are separated from the fibula, that they may not be divided by the saw, and the periosteum carefully detached, in order to favor as far as possible the subsequent production of bony material. After the ligamentous connections on this side have been severed, another incision is made on the internal aspect of the foot, and the tissues separated in a similar manner. The next steps in the operation are to saw off the external malleolus, and to bend the foot outward, causing the extremity of the tibia to protrude at the wound on the inner side of the ankle. The soft tissues are detached from this bony surface with great care, to avoid injury to the tibial arteries, and the articular portion of the bone is sawn off as high up as the caries extends; after which the astragalus and all the other tarsal bones that are diseased must be removed by the gouge and chisel.

Upon a critical examination of the condition of the tarsus, however, the disease is found to have invaded the bones to so great a degree that the preservation of the foot by exsection of the joint is rendered impossible, and it will therefore be necessary to perform amputation above the ankle.

In order to prevent hemorrhage during this operation, the femoral artery is controlled by digital compression, which is applied just where the vessel emerges from under Poupart's ligament; for in that situation it lies di-

rectly over the margin of the acetabulum and the head of the femur, so that the current of blood be arrested by a moderate degree of pressure against the hard bony surface.

The circular operation is a method well adapted for amputation of the lower portion of the leg, and will therefore be employed in this instance. The integument, having been divided by a long knife carried rapidly around the limb, is dissected from the underlying muscular structures, and turned backwards like the cuff of a coat; which eversion can be facilitated by making a vertical incision on the side of the flap. After this procedure the muscles are incised on a level with the retracted cutaneous flap, and, having been previously separated from the bones, are drawn back by a retractor in order to permit the application of the saw some distance above the joint where the muscles have been divided. In performing this step of the operation, it is important to saw through the fibula first, since it is the smaller bone, and would probably be splintered if left until the tibia had been divided, and to take care to inflict as little injury as possible upon the periosteum, for the danger of necrosis is in proportion to the extent of laceration that this membrane suffers. Hemorrhage is arrested by ligation of the anterior and posterior tibial and interosseous arteries, the edges of the flap brought together by sutures, and the wound dressed with an oiled compress retained by means of adhesive strips.

On dissection of this foot which has been removed, it is found that the calcaneum and all the other bones of the tarsus, as well as the proximal extremities of the metatarsal bones, are carious. This proves conclusively that excision of the ankle would not have been advisable in this instance; for the impossibility of removing such an extent of carious bone with a prospect of bringing the healthy portions into apposition is sufficiently apparent.

EPITHELIOMA OF THE FOREARM—REMOVAL OF THE DISEASE BY AMPUTATION OF THE ARM.

Henry M., aged 31 years, had, when a child, his right forearm crushed in a grist-mill, without, however, any injury being done to the bones. The wound did not heal, but took on epithelial disease, and now, twenty-three years since the receipt of the original injury, the entire forearm is a mass of epithelial cancer, which, having first attacked the skin, has, during its progress, invaded the deeper tissues of the limb, rendering amputation of the arm necessary for the removal of the disease.

Its removal is certainly demanded, for the patient is subject to frequent and copious hemorrhages from the diseased structures, which have rendered him exceedingly feeble, and, if continued, may lead to a fatal issue. It is probable that there is also encephaloid disease present here, for epithelioma is prone in its later stages to assume this character; which form likewise makes its appearance quite frequently at the cicatrix left after the removal of an epithelial cancer.

This man's arm from the elbow to the wrist is one enormous, unhealthy-looking, fungating ulcer, and discharges a thin sanious fluid; while the hand is swollen and greatly distorted by the involvement of the muscles of the forearm in the ulceration.

Epithelioma, canceroid, or epithelial cancer, as the affection is variously denominated, most frequently attacks the lower lip, the tongue, the anus, the rectum, the vagina, and similar mucous and cutaneous structures, but is not limited to these tissues, for it is occasionally found invading also the muscles and bones. Its cause is not understood, though not infrequently it is traumatic, as in the present instance, and in a case where I amputated in this room at the shoul-

der-joint, on account of a large epithelial ulcer originating in the scar of a burn received a number of years previously. The affection is slow in growth, and usually begins as a tubercle or warty excrescence, which subsequently, assuming ulcerative action, extends in every direction, often committing frightful ravages upon the surrounding parts, and sparing in its progress not even bone or cartilage. The pain accompanying the disease is lancinating, and frequently very severe, resembling in a marked degree the characteristic pain experienced in the progress of scirrhus.

The only operation to be performed for the removal of the morbid growth in this case is amputation of the arm about midway between the elbow and shoulder, which will be done by the flap method. In amputation by this method the flaps may be formed by transfixion of the limb and cutting outwards, or by carrying the knife from the external surface inwards towards the bone: the former of these is the preferable and more expeditious mode of operating in the arm and thigh.

This long amputating-knife is therefore pushed through the tissues from one side of the limb to the other, in close contact with the bone, and carried downwards until sufficient length has been given to the flap, which is finally completed by turning the edge of the knife and bringing it to the surface in such a manner as not to form a thin narrow extremity. Then the internal flap is made in a similar manner, and, the brachial artery having been seized by an assistant as soon as it is severed, both flaps are retracted by the same assistant, in order to allow the knife to be carried around the humerus, to divide the periosteum and any remaining muscular fibres, and to permit the application of the saw. When the limb is very muscular, it is advisable to retrench the flaps by removing slices of the muscles, for this manipulation gives a more seemly stump and renders it better for the adaptation of an artificial limb. The arteries are now ligated, having been previously isolated so that nothing but the vessel itself is included within the ligature, and the nerves are drawn out and cut off high up, in order to prevent the occurrence of neuralgia and neuromata that might be produced by pressure upon their divided extremities.

The wound will be left exposed to the air for a couple of hours, until the surface becomes glazed, and then the edges of the flaps will be brought into apposition by sutures and narrow adhesive strips; but no dressing other than this will be applied, because by causing the retention of the fluids secreted it might interfere with the process of cure.

NEW TEST FOR ALBUMEN (Boston Medical and Surgical Journal, October 23, 1873).—Picric acid has been recommended as a test for albumen. If a drop of the fluid to be examined be allowed to fall into picric acid, it sinks through, and, if albumen be present, leaves a white streak. Dr. Bowditch has found that two drops of egg-albumen added to 20 c. c. of urine gave a slight reaction with heat, a distinct one with nitric acid, but none with picric acid, and that on increasing the quantity to four drops only a feeble reaction was obtained.

CHILBLAINS.—Mr. Fergus recommends sulphurous acid in this affection. It should be applied with a camel's-hair brush, or by means of a spray-producer. One application of this usually effects a cure. The acid should be used pure. A good wash for hands or feet affected with chilblains is sulphurous acid, three parts; glycerin, one part; and water, one part. The acid will be found particularly useful in the irritating, tormenting stage of chilblains.—Druggist's Circular.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, DECEMBER 13, 1873.

EDITORIAL.

WHITHER ARE WE DRIFTING?

TO say exactly how low the American medical profession is to be sunk in the eyes of the people by the exhibitions offered in our courts of justice would require the voice of the prophet; but to perceive that we are sinking day by day lower and lower needs no "second-sight." Not long since, we heard a prominent lawyer in this State assert that he could get some doctor or doctors to swear to anything. Of course we contradicted, but of course we felt that there was a large measure of truth in what he said. It was with a sense of real shame that we awaited some taunting reply to our denial, expecting to be asked to reconcile the positive statements of the chief medical witness in the McFarland defence with his precisely opposite and equally positive printed opinions in regard to emotional insanity. Fortunately, our legal opponent was not so well posted as he might have been.

The Stokes-Fisk case has closed, and, amid the rush of events, under the shadow of the trials of the prince of plunderers and his followers, will soon be merely a matter of history to the general public. Unfortunately, the medical testimony given at the trial will be no less a matter of history. Seven doctors, most of them men of the highest rank in the profession, having attended the wounded Fisk during his lifetime, were at the trial confronted by Professors in medical colleges, by physicians supposed by the people to be representative, swearing with greater or less positiveness that not Stokes but

the doctors killed Fisk,—not the pistol but the hypodermic syringe sped the fatal bullet. Really, to see our exalted cotemporary the *New York Medical Record* searching around to find the reason that the profession is sinking so in public esteem, whilst such scenes are enacted before it, seems to us quite amusing.

Still more recently come tidings from the far West of similar degradation. This time it is not life, but property, that is at stake. It seems that a gentleman completed ten days before his death a will which showed that he called to mind all the members of his family, various persons to whom he had become attached, and several purposes which he had strongly favored during life. It was proven beyond cavil that there was a reason for every one of his numerous bequests, such as was compatible with complete soundness of mind; that he was ten days in making the will; that he continued to speak of its dispositions afterwards for several days; and that no one of the several persons about him—physicians, personal friends, one or two clergymen, and the drawer of the will—observed the slightest wandering at any time, or any remark "sounding to folly."

Yet some eight or nine doctors, including one Professor, were found who testified that the man was incapable of making a judicial will; that he must have lost, at the time of the completion of the instrument in question, all power of conscious and continuous thought; that he must have been incapable of transacting any business whatever. Why? Because carbon must have been retained in his blood!—since he had died of some pulmonary disease, and at post-mortem examination the lungs were found to have lost, through induration, two-thirds of their breathing-capacity.

WE do not believe that doctors are often dishonest in their statements on the witness-stand; but we do believe they are not rarely culpable in assuming the possession of knowledge that they do not have, and sometimes lend themselves, unconsciously, to the suppression of a part of the truth. The surroundings of medico-legal practice in our American courts are excessively bad. The specious pleading of lawyers, the demands of sympathy, the grinding force of an active public opinion, the chance of a notoriety which weak minds sometimes mistake for fame, the temptations of large fees, are of such power as to be resisted only by those strong not only in moral integrity, but also in their personal knowledge that they have studied the subject to the bottom. Yet

we have known prominent practitioners of medicine, ignorant of medical jurisprudence or of the subject under consideration, "cramming themselves" for an opinion which should turn the scales of justice when life itself hung in the balance.

In what way it is to be achieved we confess we do not exactly see, but, unless we are willing to share the public opprobrium which the present customs are rapidly producing, something must be done to create among us medical jurists, and to have some law or general medical opinion that shall prevent ignorant men, or wise men ignorant of the especial subject, from disgracing the profession on the witness-stand.

A PSYCHOLOGICAL PHENOMENON.

TO those of our readers who are fond of psychological studies the present article is addressed. Once, when serving as *interne* in a hospital under Prof. Gross, our learned chief said, "Give this patient so-and-so." "The man came in yesterday, and I ordered that for him then," was the reply. Quickly came back the answer, "You see, doctor, great minds flow in the same channel." Our psychological curiosity is on the same wise.

Most of our readers will no doubt remember our editorial of November 8 on Professional Advertisements. Curiously enough, the editor of the *Chicago Medical Examiner*, in the issue of that journal for November 15, discourses upon a similar topic, and still more curiously do his sentences run parallel with ours, as is witnessed by the following paragraphs:

"It has been freely asserted that the established physicians who constitute the Council, desiring to maintain the undisputed possession of their respective cocklofts, have kicked away the ladder up which they have climbed. One 'medicus' asserts that to stop advertising his books would 'retard his advance in practice ten years, and keep him starving,' and pointedly calls attention to the fact that the works of Mr. Curling, President of the College, have been advertised to such an extent as to make Curling and testis household words in the community, and consequently to establish their author. Another correspondent alludes pleasantly to the circumstance that the London *Lancet*, which has strenuously upheld the Council, placards the railway stations with the titles of communications on 'Tumors of the Womb,' 'Rectum,' and other subjects generally supposed not to offer edifying reading for mixed companies of ladies and gentlemen."—*Philadelphia Medical Times*.

"It is claimed by some that the established physicians, who constitute the council, desiring to maintain undisputed possession of their respective cocklofts, have kicked away the ladder up which they have climbed. One 'Medicus' asserts that to stop advertising his books would 'retard his advance in practice ten years, and keep him starving;' and pointedly calls attention to the fact that the works of Mr. Carling (*sic*), president of the college, have been advertised to such an extent as to make Carling (*sic*) and testis household words in the community, and consequently to establish their author. Another correspondent alludes pleasantly to the circumstance that the London *Lancet*, which has strenuously upheld the council, placards the railway stations with the titles of communications on 'Tumors of the Womb,' 'Rectum,' and other subjects generally supposed not to offer edifying reading for mixed companies of ladies and gentlemen."—*Medical Examiner*.

We commend this to the attention of all students of psychology, of all collectors of coincidences. We explain it by the wise saying of Prof. Gross, and warm our "*amour-propre*" with the inevitable deduction.

THE case of operation for *aneurism* by Dr. Levis, which we have editorially commented on once or twice, terminated fatally. Dr. Levis has promised us a full report of it.

The case of *ovariotomy* reported some little time ago as part of Professor Gross's clinic also had a fatal termination.

CORRESPONDENCE.

LONDON LETTER.

[From Our Own Correspondent.]

Esmarch's Bloodless Method of Operating—The Art of Gargling in the Larynx—Hospitalism—Intended Discussion at the Clinical Society of London—Sir Henry Holland—His Fortune—His Funeral—The Court Appointments—Dr. Burrows—Dr. Sieveking.

LONDON, November 14, 1873.

A GREAT deal of interest has been excited among metropolitan surgeons by the introduction here of an improved method of preventing hemorrhage in surgical operations, known as Esmarch's bloodless method. It has been introduced by Professor Esmarch, of Kiel, the well-known son-in-law of Stromeyer, and one of those careful, exact, and able observers, every one of whose publications is always worthy of careful study. Esmarch's method is so great an improvement on all previous efforts in the same direction, of which there have, of course, been many, as to be entitled to be considered an invention of the highest surgical importance. Of course many surgeons have endeavored, by systematically elevating a limb before operating on it, to empty it of blood, as well as so to restrict the access of blood by pressure on the main arterial trunks as to reduce the shock by loss of blood to a minimum; but the success has always been more or less imperfect. By the adoption of Esmarch's method the loss of blood is reduced to insignificance; and, what is hardly less important, operations on the limbs requiring careful dissection are performed with as little embarrassment from hemorrhage as if the surgeon were actually engaged on the dead subject. The method has been very extensively tried here. It was first described in the *London Medical Record*, from the data of Esmarch, Billroth, and Meissel, by Mr. William MacCormac of St. Thomas's Hospital, who at the same time announced his successful application of the method; and subsequently in the same journal (No. 42, October 22) a full translation was given of a lecture published in *Volkmann's Sammlung*, in which the whole method and its applications are fully discussed. It has come into very general use here in consequence, and is so absolutely free (as far as hitherto observed) from any bad conse-

quences and so fertile in advantages that it seems likely to take at once a permanent place among surgical procedures.

The mode of proceeding is graphically described by Esmarch himself, as follows:

"While the patient is being chloroformed, we wrap the leg in waterproof varnished tissue-paper, so that the pus from the sinuses may not soil the bandages; then, with these elastic bandages, made of india-rubber webbing, we envelop each leg from the tips of the toes to above the knee, and, by equal compression, force the blood out of the vessels of the limb. Immediately above the knee, where the bandage ends, we apply this piece of india-rubber tubing four or five times round the thigh, drawing it very tight, and fastening the hooks which you see at one end to the brass rings at the other. The india-rubber tubing compresses all the soft parts, including the arteries, so completely that not a drop of blood can pass into the part which has been tied off. It has this advantage over all tourniquets, that you can apply it to any part of the limb, and need not give yourself any trouble about the position of the principal artery. Even in the most muscular and fattest individuals, you can perfectly control the flow of blood in this simple way.

"We now remove the india-rubber bandage which was first applied, and the varnished paper lying under it; and you see that both legs, below the compressing tube, perfectly resemble the legs of a corpse, presenting in their pale color an almost dismal contrast with the rosy hue of the remaining parts of the surface. You will see, too, that the operation will be in all respects like one on a dead body."

By employing this method, exploratory proceedings to ascertain the extent of disease before deciding finally the variety of operation to be performed (excision, partial excision, amputation) are much facilitated. The whole matter is one of great interest, and is sure to attract the attention of surgeons throughout the world, who will, no doubt, succeed in improving on the results of Professor Esmarch.

Another foreign physician has endeavored to interest us by demonstrating on his own person very effectually the fact that by a modification of the method of gargling it is perfectly easy to introduce the fluids employed into the larynx, and to fill the supraglottic cavity of the larynx completely, so that the white vocal cords may be seen firmly contracted below the liquid, shining through it and bathed in it as to their upper surfaces. The common fallacy is to suppose that the epiglottis so guards the larynx that no fluid enters it. M. Guinier not only demonstrates the opposite truth, but shows how laryngeal gargling may be erected into a regular therapeutic method. His directions for introducing gargles into the larynx are,—

1. Slightly to raise the head.
2. To open the mouth moderately.
3. To protrude the chin and the lower jaw.
4. To phonate the diphthong *æ* (in the highest upper notes).

He asserts that he finds little trouble in teaching his patients at the baths of Cauterets to adopt this method of gargling, and that by doing this and *not* throwing back the head, none of the gargle is swallowed. What is quite certain is that Dr. Guinier himself has acquired the art in the most perfect manner, and goes through half an hour of gargling, demonstrating with the laryngoscope, with the greatest ease and without experiencing any annoyance. But practice certainly counts for much in such a performance. Singers and persons of some intelligence could, no doubt, without much difficulty, acquire this method of gargling; and for many singers, clergymen, and others, it is an art probably quite worth cultivating. But it is not given, I imagine, to every one to "gargle in his larynx," and certainly to few to accomplish the process with so much evident enjoyment as this enthusiastic physician.

The discussion on hospital statistics continues, and is, as I predicted, widening its area. The two former assistants of Sir James Y. Simpson, Dr. Lauchlan Aitken and Mr. Lawson Tait, are entering the field in defence of his statistics relating to hospitalism, but only with the effect of materially weakening such authenticity as formerly attached to the documents. Mr. Tait reveals the unexpected fact that one at least of these was altogether a forgery. He promises, however, to publish the whole of the original documents in a volume. This will have the effect of showing whence they were derived, and how far they cover a complete field, or represent the selected results of surgeons whose cases were so favorable as to make them anxious to publish them; but it will not remove the objection that they do not represent the absolute mortality of any one district, and especially not of any old town district. Mr. Prescott Hewitt intends, I hear, to arrange a "field-day" on the subject at the Clinical Society of London, of which he is President, for the purpose of inducing the leading surgeons of London to follow an example which he proposes to it, of stating the amount of "hospital disease" prevailing, in their experience, after operations in private houses, a converse side of the question well worth discussing, and which will throw a great deal of light upon the points at issue. Meanwhile Mr. Erichsen, who opened the fire by his introductory address, in which he quoted, endorsed, and pointed the moral of Simpson's charges against hospitals and hospital surgeons, is somewhat in trouble. The committee of University College are a little anxious at the unnecessary loss of life to which he points: they have called upon their surgical staff to assume whatever may be their share of responsibility in the matter; and so Mr. Erichsen will have to settle as to the facts with his colleagues, and as to the conclusions with his committee. He is quite strong enough and skilful enough to steer through the storm which he has raised, and the result can but be beneficial to science.

Sir Henry Holland leaves a fortune amounting to £9000 a year to his children. He died full of honors and of friends; and yet it must be mentioned, as a satire upon the gratitude and affection of the great, that this

eminent physician, to whom more than one generation of great persons are deeply indebted for various good offices, was carried to the grave almost unattended, except by his immediate family. For more than thirty years Sir Henry had been but little seen in professional circles, and was personally almost unknown to more than a very few of the present race of metropolitan physicians. He had interested himself but little in professional affairs. It is not surprising, therefore, that few medical men followed him to the grave. He was buried almost before they were aware that he had passed away. But it is not a little surprising that his wide circle of friends among the greatest personages cared so little to show a last mark of respect to his remains.

His death left vacant the court office (a nominal one) of physician to the Queen. This has been filled by the appointment of the existing President of the College of Physicians, Dr. Burrows. As a sort of consolation to Dr. Sieveking, who has been slightly treated by the Prince of Wales, and has never had the solid benefits of his nominal position as physician to the Prince and Princess, he has now been promoted to the honorary office of extraordinary physician to the Queen, vacated by Dr. Burrows. These are all paper appointments, and rather raise a smile than confer any solid distinction. The actual attendant of the Prince is Sir William Gull, and of the Queen, Sir William Jenner; while to fill Sir William Jenner's place when he is unable to attend, Dr. Wilson Fox and Dr. Marshall have been appointed to the household offices. There is always a good deal of hollowness about court appointments, and not unfrequently, as has been the case with Dr. Sieveking, they lead to humiliation and annoyance rather than to any real advantage. Many London physicians think that they might with advantage be dispensed with.

THE PREVENTION OF LOSS OF BLOOD IN SURGICAL OPERATIONS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

IN looking, a few days ago, over the *Medical Times* of November 22, I read with great avidity your extract from the *British Medical Journal* of October 25, concerning the mode of preventing the loss of blood in surgical operations, as enunciated and practised by Professor Esmarch, of Kiel. I had, however, not read very far before I found myself in contact with an old acquaintance, and then it occurred to me, what we all have seen so often in print, that history repeats itself, not only in politics, in statesmanship, and in the arts and sciences, but above all, and in a most wonderful manner, in our own profession. It is seldom that one picks up a medical journal which does not contain some startling novelty as old as the hills, set forth with all the enthusiasm of a grand discovery, the happy sciolist never dreaming that he was announcing, perhaps for the fortieth time, what had long been forgotten, or, more properly speaking, what so few had learned and appreciated when first put in print, in so decided and

positive a manner that he who runs may read. It is to this class of professional men that the sentiment of Seneca applies with peculiar force, determined, as they seemingly are, that their knowledge shall shine before the world with a special lustre: "*Qui sibi amicus est, scito hunc amicum omnibus esse.*"

I had not proceeded very far in the perusal of the lecture of the distinguished Professor of Kiel, when I said to myself, "Here is a broad field upon which the medical teachers, hospital surgeons, and medical editors of the United States may display their knowledge before their pupils and their readers, certainly for the next twelve months, if not for a much longer period." I inwardly congratulated them upon having fallen upon something that was really new, and likely, for a time at least, to take the place of the carbolic acid dressing and other miraculous procedures. I was not disappointed. Already the journals of this and other countries come to us loaded with the praises of the "new method of preventing hemorrhage in surgical operations," and, as a natural consequence, the name of Esmarch is upon the tongue of every physician and student. Esmarch, always a man of progress, has covered himself with glory; like Byron, he woke up one morning and found himself famous; and already our countrymen are prepared to contribute largely towards the erection of a statue in honor of the man who has achieved this wonderful discovery,—a discovery before which that of the ligature by Ambrose Paré and that of acupressure by Sir James Y. Simpson literally blanch and fade into insignificance. Only the other day, as I was credibly informed, one of our hospital surgeons, one of the most dexterous and beautiful operators in this goodly city, astonished his pupils and his learned confrères by cutting off a thigh for a poor fellow with the aid of this "preventive method" with hardly any loss of blood; and so thoroughly saturated is the medical mind, at this moment, in Philadelphia medical circles, with this wonderful discovery that no other topic is tolerated. The moment a man utters the words "carbolic acid," alludes to the latest improvement in the obstetric forceps, or hints at the best and safest method of securing the pedicle in ovariectomy, the offending individual is at once coughed down, pronounced an old fogey, or silenced by the cry, "Hear, hear, hear!" Now and then you may hear one, more bold than the rest, scream out, in a voice and tone that might charm Mahomet, "There is but one God, and Esmarch is his prophet." In Europe the same enthusiasm prevails. The medical journals everywhere speak of the "preventive method" as one of the greatest triumphs of the age, as a most astounding discovery. A surgeon of one of the great London hospitals, writing to one of his confrères in this city, gravely asks him whether he has made himself familiar with this mode of preventing hemorrhage in surgical operations, adding that it is regarded with the greatest favor by all his colleagues, and that everybody is making it the theme of conversation, of discussion, and of merited praise.

This "new method," as every reader of the *Times*

knows, simply consists in pressing the blood out of the part to be operated on, while it is held at a right angle with the body, and preventing its return until the knife has done its work. The patient being brought under the influence of chloroform, a bandage of india-rubber webbing is drawn tightly round the limb from its distal extremity upward, when the parts immediately above are firmly constricted with a piece of india-rubber tubing cast four or five times around the limb, the ends being secured together by hooks and chains. The elastic webbing being next removed, the operation is proceeded with, hardly any loss of blood following.

In a case of necrosis of both legs, described at length, in which this process was employed, the Professor and his assistant operated simultaneously upon the two limbs, the flow of blood from each bone hardly amounting to a teaspoonful, and the man, we are told, at his own request left the hospital on the twenty-first day.

The method of treatment here briefly described is, as the German Professor kindly informs us, applicable only to the extremities, and to the penis and the scrotum. Obviously, it is not adapted to operations upon the head, neck, or trunk; although he has suggested that advantage might be derived from encircling, as a preliminary step, one or more of the limbs with elastic tubing, so as to retain a store of blood in them, to be used in case of emergency from exhaustion by allowing the blood to re-enter the circulation.

"There is nothing new under the sun," is a saying as old as it is true. This mode of preventing hemorrhage in surgical operations is certainly no novelty in this country, whatever it may be on the other side of the Atlantic. We have heard within the last few days a surgeon of large experience declare that he had employed it upwards of thirty years ago; and in the first edition of Professor Gross's *System of Surgery*, published in 1859, vol. i. p. 663, the author, in speaking of amputations, gives, among others, the following instructions: "A third assistant takes charge of the tourniquet, but before applying it care is taken to empty the superficial veins by raising the limb and pressing it from above downwards; or, instead of this, the limb is *tightly* bandaged just before the operation. Such a precaution, however, is only of *material* moment when the patient is very feeble, and therefore ill able to bear the loss of blood."

In the above short sentence is obviously comprised, as if in a nutshell, the whole of this new and much-vaunted method of preventing hemorrhage in surgical operations. Professor Gross does not describe the procedure as a novelty, but as one so well known as not to require any special emphasis or illustration. He had not only repeatedly employed it himself in hospital and private practice, but he had witnessed its happy effects in the hands of others so repeatedly that it had ceased to impress him as a novelty when he indited the above sentences.

The German Professor presses out the blood, and then applies a gum-elastic bandage and encircles the limb with four or five turns of india-rubber tubing.

It may be asked, What is the difference whether the roller, when *tightly* applied, is an ordinary bandage or a gum-elastic one? Has not an ordinary roller, when tightly applied to a limb, and its effects have not been properly watched, often caused gangrene from the arrest of the blood in the arteries and veins, deep as well as superficial? Is there any difference in the circular constriction of a limb when made with a tourniquet or india-rubber tubing? There may be magic in elastic material thus used, which an ordinary plodding mortal may not have sense enough to perceive or to appreciate. If there is any actual difference, it is the difference between "tweedle-dum and tweedle-dee."

As was stated before, we shall hear much of this new method of preventing hemorrhage within the next year or two. The medical journals will teem with accounts of it. Numerous modifications will soon be suggested, as so many pegs to hang a little notoriety upon. Many will strive to excel in this particular direction, and not a few will regret that the method cannot be applied with safety to the "encephalic extremity," the contents of which will be not a little puzzled and perplexed in the approaching lucubrations and controversies. It is easy to foresee that the "carbolic acid treatment" will for a time be thrown into the shade, and that many wonderful things now agitating the professional mind will be swallowed up by the new method of preventing hemorrhage in surgical operations. The wounds left after operations thus performed will, we shall no doubt be told, always unite by the first intention; erysipelas and pyæmia—those frightful enemies of the human race—will no longer torment our patients; and the life of many a poor sufferer will be greatly prolonged by this astounding transatlantic discovery.

UNGUIS.

GLEANINGS FROM OUR EXCHANGES.

DEATH FROM CHLOROFORM IN BOSTON.—On November 10, in Boston, a lady to whom Dr. Eastham, a practising dentist, was administering an anæsthetic, suddenly expired. The following report of the circumstances of the case, and of the coroner's inquest, is condensed from the *Boston Medical and Surgical Journal* for November 20 and 27:

Dr. Eastham testified that the deceased had been his patient for twelve or fourteen years, during which time he had on several occasions given her anæsthetics, chloroform, ether, and gas, both separately and in combination.

On the forenoon of November 10, she came to his office for the purpose of having a tooth extracted, and insisted upon taking ether. He made a mixture of chloroform and ether, containing less than half chloroform by volume, poured about a teaspoonful on a cup-sponge, and began the administration, first holding the sponge a little distance from the nose, and then moving it nearer. After she had breathed it for two or three minutes (or, according to the same witness at a later stage of his examination, from a minute to a minute and a half), he told her he was about to proceed. She shook her head, as if to say that she was not ready, but he took hold of the tooth and extracted it, during which operation she straightened back, groaned, and screamed

a little, as if in pain, and afterwards went into a sort of hysterics and became rigid. At this point he did not notice her lips or try her pulse, but observed that her eyes were set wide open, like those of one in a spasm. He seized a napkin moistened with water and gave her a splash on the forehead; she seemed to revive, and a flush came over her face, upon which he sat her up and applied ammonia-water to her nose. Her dress was then loosened, but as she became pale again he sent out for assistance. Another dentist arriving, they proceeded to undo her corsets and rub her spine, continuing the application of strong ammonia. During this time, about fifteen minutes, she was sitting up in the chair; but as soon as a physician had been procured she was removed to the waiting-room and laid down, but she had then stopped breathing; artificial respiration was employed, and a battery was used until it was evident that she was past all restoration. This witness testified in addition that there are two peculiar and perfectly distinct shades from the use of anæsthetics, one for faintness and one for sick stomach, and that he thought the pallor in this case was of the former variety. He never felt the pulse while producing anæsthesia, but watched the temporal artery. He did not consider that chloroform, if given on a sponge with plenty of fresh air, was any more dangerous than ether, but supposed it would decompose the blood more quickly; had not fully anæsthetized her, because he considered her to be somewhat lacking in vitality; does not feel any anxiety when about to administer ether, chloroform, or the mixture; preferred the latter, because the patients are not so noisy or excited under its influence; used Squibb's chloroform, and Powers & Weightman's ether.

A friend of the deceased testified that two days before her death the latter appeared in excellent health, that she had never known her to complain of trouble in her heart, that she dressed loosely, and was not then nursing her child.

A lady who had accompanied the deceased to the dentist's confirmed Dr. Eastham's account: she had insisted on taking ether, but nothing was said about chloroform.

Dr. Osgood, the dentist who came when assistance was sent for, testified that he found her sitting in the chair, inclined forwards; her corsets were quite tightly laced; he could not detect any pulse or respiration, and believes she was dead at the time of his arrival.

Dr. R. H. Fitz, Pathologist to the Massachusetts General Hospital, read his account of the autopsy, made twenty-one hours after death. Rigidity was well marked; skull-cap and dura mater normal; longitudinal veins empty; moderate amount of blood in the veins of the arachnoid. Blood-vessels at the base of the brain contained but little blood; cerebral substance firm, with much less blood than usual. Heart and aorta unusually small; the cavities containing dark fluid blood of no unusual color or odor. Lungs of a bluish-red color; the posterior dependent portion quite dark; tissue contained air, and a somewhat increased amount of blood; no special degree of œdema; kidneys, liver, and uterus normal, but with rather more blood than usual. The examination gave no evidence of recent disease of any of the organs, or of chronic alterations sufficient to account for death; the fluid condition of the blood, its diminution in the brain, and its increase in the thoracic and abdominal viscera were abnormal, and might have been the result of various causes; the diminished size of the heart and aorta was probably of congenital origin. The blood is found liquid after death in cases of asphyxia, of poison from certain gases, and of some very malignant forms of disease in which decomposition is extremely rapid.

Dr. E. S. Wood, acting Professor of Chemistry at the Harvard Medical School, gave an account of his analysis of the anæsthetic used. The odor resembled that of ether mixed with chloroform, the latter being strongly perceptible. Its specific gravity was 1.043, which corresponds to that of a mixture of six parts by bulk of ether with four of chloroform, if allowance be made for an increase in the density of the two when mixed. The liquid answered to the tests both for chloroform and ether; it contained no hydrochloric or acetic acid, and no chlorine, showing that both the ether and chloroform were free from any deleterious ingredients, a small amount of alcohol only existing as an impurity.

The witness stated that the only statistics he had seen relative to the mortality occasioned by the use of ether or chloroform, or a combination of the two, were some which were published in Chicago in 1870, and which were copied into the last annual report on the practice of pharmacy and toxicology. Roughly, the proportion of deaths to cases in ether was one in twenty-five thousand; to cases in chloroform, one in twenty-five hundred; to cases of a mixture of the two, about one in five thousand. The smallest dose of chloroform reported as causing death was from fifteen to twenty drops by inhalation; one drachm taken into the stomach; one drachm of a mixture containing one part of chloroform to four of ether, by bulk. It has sometimes, but rarely, been possible to detect chloroform in the blood.

Dr. Henry J. Bigelow testified that, having heard the testimony, he believed there was no question but that the deceased had died of the inhalation of chloroform. The amount of ether in the mixture could not possibly cause death. He had never known of a case of death from ether properly administered. Chloroform has besides its narcotic power some very poisonous influence, which acts on the system, and in which it differs from ether.

Drs. Cabot, Clark, Gay, and Hodges testified to the same effect.

On the next evening the jury met, and presented the following verdict:

"That Mary F. Crie came to her death on Monday, the tenth day of November, 1873, between eleven A.M. and one P.M., in the office of Dr. Charles Eastham, a dentist, No. 25 Tremont Street, Boston, and that her death was caused by the inhalation of chloroform, administered in a mixture of chloroform and ether by the said Dr. Eastham. The jury uses this opportunity to caution the public against the inhalation of so dangerous an agent as chloroform for the production of insensibility to pain. In the opinion of the jury, the inhalation of sulphuric ether is safe, while the inhalation of chloroform, either alone or mixed, is always attended with danger."

It was signed,—Ezra Palmer, M.D., John A. Lamsom, M.D., George Fabyan, M.D., George Lotz, M.D., Thomas Restieux, and Thomas Dolover.

EXCISION OF THE TONGUE (*The Lancet*, November 8, 1873).—In a case of cancerous ulcer of the tongue, Mr. Gant removed the organ in the following manner, leaving the floor of the mouth entire. An incision was made through the cheek on the left side, from the angle of the mouth to the junction of the ramus and the body of the bone; the tongue was seized with a forked vulsellum and drawn forwards and upwards; two curved aneurism-needles were passed through the base of the organ from before backwards, and a strong écraseur was then looped around the base, below the needles, which thus kept the loop well down around the whole tongue. It was worked slowly, and the tongue thus completely removed in thirty-eight minutes.

FATAL CASE OF DYSPHAGIA (*The Lancet*, November 1, 1873).—Mr. E. F. Fussell reports a case of difficult deglutition occurring in a man 47 years of age, of temperate habits, and having never had syphilis or any serious illness. There was no stammering, but some thickness of speech, so that he was unable to make himself thoroughly understood, partly from the excessive flow of saliva, which was continually running from his mouth, and partly perhaps from a paralysis of the muscles co-ordinating the power of speech. For some time he had been unable to swallow solids or even semi-fluid substances: He had had no hæmatemesis or bloody stools, no albuminous urine, and no mental symptoms whatever. On trying to swallow food it returned almost immediately. He refused to have an instrument passed, and soon died of inanition. At the post-mortem examination no disease was discovered in the mouth, tongue, larynx, pharynx, upper cervical vertebræ, pneumogastric nerves, œsophagus, or stomach. The other organs could not be examined.

ACTION OF THE CINCHONA ALKALOIDS ON BACTERIA (*The Practitioner*, November, 1873).—Dr. E. Buchanan Baxter arrives at the following conclusions as the results of a large number of experiments upon the influence of the four chief alkaloids of cinchona bark over bacteroid organisms:

1. Quinia is doubtless excelled by other antiseptics, but there is no substance equal to it in antiseptic power which can be introduced into the blood in the same proportions without risk of fatal effects, if we except the other cinchona alkaloids, and the sulphate of bebeeria.

2. Quinia in such fractional doses as are capable of being introduced into the circulation exerts an inhibitory, not a toxic, action upon microzymes. It may check septic changes, it cannot destroy the organisms to which such changes are due.

3. The four cinchona alkaloids are very nearly equal in antiseptic power. Arranged in the strict order of their efficacy, they stand thus:—quinia=quinidine; next comes cinchonidine; last, though at no great distance, cinchonina. This order corresponds to that in which they have been arranged with reference to their antiperiodic power.

4. Among reputed antiperiodics, the sulphate of bebeeria seems to equal quinia in antiseptic power.

5. Among reputed antiseptics, sodic sulpho-carbolate and strychnia have a decided value, though they stand some way below quinia; sodic sulphite has a feeble though decided antiseptic value; sodic hypo-sulphite, little or none; berberin and æsculin are hardly, if at all, antiseptic; potassic picrate is almost equal to quinia, but it is doubtful whether it can be given in sufficient doses without danger to life.

MUSCULAR PARALYSIS FROM MERCURIAL ABSORPTION (*Dublin Journal of Medical Science*, September, 1873).

—Dr. A. W. Foot reports the case of a man, æt. 23, who, while rubbing red mercurial ointment into cattle affected with pleuro-pneumonia, neglected to cover his hand, and afterwards only rinsed it in cold water. The next morning the hand and arm were numb and powerless; he could not flex, extend, or abduct the hand, and had a stinging sensation in the fingers. Three weeks later the condition persisted, though it was one of great weakness rather than complete paralysis; the deltoid was not affected, nor the muscles of the upper arm; there was no atrophy. He was ordered five grains of iodide of potassium twice a day, and subcutaneous injections in the affected forearm, at first of $\frac{1}{8}$ of a grain of strychnia every second day, and subsequently of $\frac{1}{2}$ of a grain. When he began to feel pain along the course of the median nerve, the injections were discontinued, and the primary induction current of Stöhrer's battery was employed daily. He

quickly improved, and soon recovered the full power and use of his hand and forearm.

ANOREXIA HYSTERICA (*British Medical Journal*, November 1, 1873).—At a recent meeting of the Clinical Society of London, Sir Wm. Gull called attention to a form of disease occurring in young women between the ages of fifteen and twenty-three, and characterized by extreme emaciation, which was often supposed to be due to latent tubercle, mesenteric disease, or so-called atrophy. He believed the cause of the affection to be central, not peripheral, and in using the word hysterical did not wish to be committed to its strict etymological value. The clinical characteristics of this disease are those of starvation only, and the diagnosis is to be made from the slowness of the pulse and breathing, the slightly depressed temperature, and the absence of any sign of visceral disease in the chest and abdomen. In the treatment, if possible, a change in the domestic relations should be made, food should be given at short intervals, and the patients should not be left to their own inclinations in the matter. If the exhaustion reached an extreme point, external heat might be required; but the principal dependence should be placed upon controlling moral influences, and upon feeding.

MISCELLANY.

ACCORDING to the official estimates for 1873, we have the following: *Department of Charities and Corrections*: Out-Door Poor Department, \$128,066; Bureau of Out-Door Sick Poor, \$5300; Bellevue Hospital, estimated number of patients 700, \$103,370, or \$147.67 each patient; Charity Hospital, estimated number of patients 950, \$133,302, or \$140.31 each patient; Hospital for Contagious Diseases, 180 patients, \$20,667; Fever Hospital, 60 patients, \$6179; Smallpox Hospital, 175 estimated inmates, \$24,950; Hospital for Incurables, \$13,393; Asylum for the Blind, 150 inmates, \$8055; Convalescent Hospital, 250 inmates, \$22,041; Lunatic Asylum, 1300 patients, \$119,919, or \$92.25 per patient; New York City Asylum for Insane, 650 patients, \$83,026, or \$127.72 per patient; Hospital for Epileptic and Paralytic Patients, 120 patients, \$13,172; Hospital for Infants, 450 children, \$51,780, or \$115.06 per child; Randall's Island Nurseries, 650 inmates, \$61,282, or \$93.58 per inmate; Nursery Hospital and Idiot House, Randall's Island, 450 inmates, \$47,887; Inebriate Asylum, \$23,611; Reception Hospital, Centre Street, \$10,180; Reception Hospital, 115th Street, \$5920; Ambulance Establishment, \$3995; General Drug Department, salaries, \$2500. Total, \$888,595, as the estimate for the above hospitals, etc., Department of Charities and Corrections.—*New York Medical Record*.

THE AGE OF EGGS.—*The Lancet* quotes the following from a French authority as a mode of ascertaining the age and consequent freshness of an egg: Dissolve one hundred and twenty grammes of common salt in a litre of water. If the egg is one day old, it will sink to the bottom; if it was laid the day before, it will not reach the bottom; if three days old, it floats; and if more than five, it comes to the surface, and the shell projects more and more according to staleness.—*New York Medical Record*.

CAUSTICS VERSUS WEEDS.—A recent writer of a chemical turn of mind says, "Two years ago I took a large house and grounds which had been uninhabited and utterly neglected for three years. The lawn is nearly an acre in extent. Dandelions, buttercups, plantains, docks, etc., were in the ascendant. After many attempts to eradicate them, I found at last that one drop of the common strong sulphuric acid dropped upon the crown of each weed entirely destroyed it, and it will never grow again. I used one of the ribbed bottles employed by chemists and photographers for dropping poisons, and found it to answer perfectly, and it enables one to apply the acid with great rapidity. Large docks, which have hitherto never been destroyed except by digging up, are effectually destroyed by the acid."

EARLY CLINICS.—That bedside teaching was pursued eighteen centuries ago, although in no very pleasant way for patients, appears from the following lines translated from Martial:

"I'm out of sorts, but Symmachus is here,
His hundred pupils following in the rear;
All feel my pulse with hands as cold as snow,
I had not fever then—I have it now."

—*Mapother's Address, Med. Press and Circular.*

As an example of the "multum in parvo" style, we extract the following from an article in a recent eclectic journal:

"Diagnosis—'jiggers.' Prescription—sulphite of soda. Result—fixed them the first day."

CHOLERA dejections and vomit in the Dresden Hospital are received in a mixture of sawdust and charcoal, on which petroleum is then poured and the mass burned.—*Northwestern Medical and Surgical Journal.*

SPIRITUALISM is a comet with a small body of natural fact and an enormous tail of guessing, of sensation, of superstitious and ignorant fear, and of conscious and interested imposture.—*John Hall, D.D.*

COSTE, the celebrated naturalist, was almost sightless at the time of his death, having destroyed his vision with the microscope. At the time of his decease he was sixty-six years of age.

It is proposed in Italy to erect a monument to Eustachius. Few anatomists have had their trumpet so much blown.—*Boston Medical and Surgical Journal.*

DR. F. CRACE-CALVERT, F.R.S., famous for his researches upon disinfectants, died in Dublin, October 24, aged fifty-three years.

NOTES AND QUERIES.

BUCKS COUNTY, PENNA., November 28, 1873.

DR. GROSS:

DEAR SIR,—I have a great desire to study medicine, but have what seems to me a great obstacle to overcome. It is a certain sympathy with the patient, in which I am affected as much by the operation as the patient himself, producing in me a sickness over which I have no control.

I have never seen but one operation performed in your college, and that had the above effect on me. Now, will you write and tell me if this feeling can be overcome? for by so doing you will oblige me greatly.

Respectfully,
J. B. C.

Answer.

PHILADELPHIA, November 29, 1873.

DEAR SIR,—The difficulty to which you refer is more imaginary than real, and can, with a little practice, be readily surmounted. The sight of a severe surgical operation is to many persons exceedingly disagreeable, and at first sometimes even sickening. I have seen as many as three, four, and even five young men faint around me at the first few clinics at our college at the opening of almost every session since I came into the school. But in the course of a week or two nothing of this kind is witnessed, and the most delicate student is able to look with perfect unconcern at the most bloody operation.

The human mind, however sympathetic, has a wonderful faculty of accommodating itself to circumstances. When I was a student in the office of the late Dr. George McClellan, it devolved upon me to hold the basin while an older pupil bled a patient, and the result was that I became so sick that I was compelled to step out into the yard to avoid fainting. I soon got over this feeling, and I presume there are few men who have performed more severe or bloody operations than I have, or who are more self-possessed in cases of emergency. Your own case, then, you perceive, is not a hopeless one. A little determination will enable you to overcome this feeling, and it is only necessary for you to persevere in your laudable effort to study medicine, to become a great surgeon. A tender heart, so far from being an objection, is one of God's greatest gifts in a practitioner of the healing art.

When you visit the city, it will afford me pleasure to see you, and to offer you in person a word of sympathy and encouragement.

Very truly yours,

S. D. G.

Mr. C.

CHESTER COUNTY MEDICAL SOCIETY.

At the stated meeting of the Chester County Medical Society held in West Chester on Tuesday, October 28, 1873, the following preamble and resolutions, offered by Dr. Jacob Price, were unanimously adopted:

"Whereas, Since our last meeting it has pleased God to remove from a life of usefulness and honor our esteemed colleague Dr. Wilmer Worthington, and whilst we bow in all humility to the dispensation, we cannot avoid, upon this occasion, giving expression to the sorrow his death has caused in the heart of every member: therefore,—

"Resolved, That this Society has heard with deep regret of the death of Dr. Wilmer Worthington, one of its founders, and through his long life one of its most faithful and useful members.

"Resolved, That in this event our Society has sustained a loss that cannot easily be replaced; and that the remembrance of his earnest and self-sacrificing devotion to the interests of science, of the medical profession, and of humanity, should stimulate us to increased energy in the discharge of the duties that rest upon us as physicians and citizens.

"Resolved, That this Society sympathize deeply with the family of the deceased in their great bereavement.

"Resolved, That a committee be appointed to prepare a biographical notice of the deceased, to be embodied in the Transactions of the Medical Society of the State of Pennsylvania.

"Resolved, That the Secretary be directed to furnish the family of Dr. Worthington with a copy of the foregoing resolutions, and also copies to each of the county papers, and the medical journals published in Philadelphia, for publication.

"EPHRAIM HOPKINS,

"Recording Secretary."

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 2, 1873, TO DECEMBER 8, 1873, INCLUSIVE.

VICKERY, R. S., ASSISTANT-SURGEON.—Assigned to duty at Jackson Barracks, New Orleans, Louisiana. S. O. 188, Department of the Gulf, November 28, 1873.

DE WITT, C., ASSISTANT-SURGEON.—Granted leave of absence for six months. S. O. 241, A. G. O., December 14, 1873.

KIMBALL, J. P., ASSISTANT-SURGEON.—Assigned to duty at Fort Randall, Dakota Territory. S. O. 266, Department of Dakota, November 28, 1873.

SATURDAY, DECEMBER 20, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A PAPULO-SQUAMOUS SYPHILO- DERM.

Delivered in the University of Pennsylvania,

BY LOUIS A. DUHRING, M.D.,

Clinical Lecturer upon Diseases of the Skin.

THE patient whose disease we propose to consider is a well-built, strong-looking man, 36 years of age. Fourteen years ago, he says, he had a venereal sore upon the penis. This healed in a few weeks, and two months later an eruption of reddish spots and blotches appeared over his body, followed by sore throat and by pains of a darting nature in his limbs. The eruption soon subsided, but he has had relapses of a similar eruption on several occasions since. He remarks that he has been treated for syphilis at various times by several physicians. The present disease which we see scattered over his body is of four years' duration, never having left him entirely within this period. Such is a brief history of his trouble. We would describe him as having an extensive cutaneous disease, extending over the scalp and forehead, especially just below the line of the hair, about the ears, somewhat upon the back, abundantly over the chest, and lightly over the arms, thighs, and legs. It is most pronounced upon the chest and upon the scalp. Upon the chest the eruption consists of a large, irregular-shaped patch, made up of papules and tubercles closely studded together, forming here and there solid masses of disease. In places the papules and tubercles are separate, discrete, with sound skin between them. They vary in size from a large pin-head to a small pea, are markedly elevated, are not, however, acuminate or pointed, but flattened, and covered with scanty, adherent, yellowish-white scales; others are entirely free of scales, and possess a smooth, reddish surface. The color of the eruption is a livid red, especially brilliant upon the parts free of scales. Now, the disease upon the scalp we observe to be different in some of its characters. Instead of the papules and tubercles which we see upon the chest and other parts of the body, we have only a slightly-elevated, very imperfectly-defined, reddish infiltration or deposit in the skin, covered extensively with scales and sebaceous matter, running over the scalp in a serpentine course. If you attempt to follow the track of the eruption, its irregular, winding, broken trail is difficult to trace. It possesses a linear form and a serpentine, twisted course. Eruptions in the scalp having this aspect must always be regarded as very suspicious of syphilis, for this is the favorite outline in which syphilis of the scalp tends to manifest itself. The scales are very thin, and at the same time very adherent, and are detached with difficulty; they cannot be shaken off loosely, as in psoriasis or sebor-

rhoea. There is no moisture or ulceration whatever about the scalp, or indeed anywhere upon the skin. Our patient is a carpenter, and sweats freely when working, at which time, he tells us, the eruption itches and annoys him. It is a very commonly received idea that syphilitic eruptions do not cause itching; that these diseases of the skin are always free from this annoyance. Now, this idea is true to a certain extent, but it must not be accepted without reservation, for the degree of itching in any case of cutaneous disease will depend materially upon existing circumstances. Thus, when estimating the amount of itching present, allowance must be made for temperament,—whether the individual possess an irritable, quick, nervous habit, or whether he be indifferent and stolid. A nervous, excitable patient will incline to rub, scratch, and irritate the disease, whatever it may be, and so induce additional, artificial, nerve-irritation.

The seat of the eruption likewise influences the amount of itching. The occupation and the general habits of the patient also often afford a clue to this symptom. If you desire to know exactly what degree of itching a certain manifestation upon the skin causes upon an individual, it will be necessary to inquire minutely and with questioning into all manner of detail: whether the symptom is constant, periodic, or irregular in its course; whether the occupation, or exposure to cold or heat, sweating, and other conditions, influence it in one way or another. Copious sweating, the excretion coming in contact with diseased and abraded skin, is generally the source of some itching and burning in certain diseases, particularly in some syphilitic eruptions; and the annoyance in the case before us may be explained in this way. I must not be understood as saying that syphilitic eruptions always cause itching, for the rule is that they do not give rise to this symptom. I do desire, however, to call attention to the fact that itching may be present with some syphilitic eruptions, and that syphilis must not be excluded because a disease of the skin itches. But to return to our case. If we examine closely and endeavor to study the arrangement of the eruption upon the body, we shall see that the larger patches are made up of numerous smaller ones, which have coalesced and encroached upon each other. There exists also a tendency to a uniform arrangement of the individual papules: they are placed together in a crescentic or semicircular form. This grouping which the papules are wont to assume must not be lost sight of, for it is of diagnostic value. Experience teaches us that the papules and tubercles of syphilis are prone to take on this arrangement, so that when we see it in diseases like the present we are at once suspicious of syphilis. It is readily recognizable in most cases, though not always so well marked.

The history in our case happens to be a clear one, from the chancre, through the various symptoms, to the eruption before us; but even had we no history of the initial lesion, or indeed of any venereal trouble, as is so often the case, we should

be fully justified in making the same diagnosis with quite as much assurance, for the skin manifestation alone is sufficient for our purpose. Such an eruption is always syphilis and can be nothing else. It is due to one cause, and only one, the inoculation of the virus syphilis in one way or another. How the inoculation has taken place, whether through coition or other ways, it matters not, so far as our diagnosis is concerned. Syphilis is a most subtle poison, nor are the various avenues and ways of contagion in many cases which come under our notice by any means clear. But, having certain manifestations upon the skin, we are always warranted in saying that the disease is positively due to syphilis and to no other cause, permitting the history to go for naught. For, gentlemen, the lesions of the skin due to syphilis are no longer involved in obscurity; they are known, are accurately described, and readily discerned when they show themselves. Our knowledge of the various forms of disease which the integument of the body assumes is becoming more definite year by year, and dermatology and syphilology have each been elevated by the hard labors of those who have given themselves to this task.

In making the diagnosis of our case, the fact must not be forgotten that there are diseases with which it may readily be confounded, if care and attention be not exercised. But there is one non-syphilitic affection in particular which frequently resembles papulo-squamous syphiloderms, and to which I desire to call your notice. I refer to psoriasis, or psoriasis vulgaris as it is also called, a disease in no way connected with syphilis, which, however, in some of its forms and stages looks at a glance not unlike it. On the other hand, certain of the squamous syphiloderms sometimes resemble psoriasis so much as often to be the cause of error in diagnosis.* These two distinct cutaneous manifestations, though at times so alike in appearance, let me here state, are absolutely never in any way connected with each other. They are widely separate processes. They are different pathological changes, and hence can bear no relation to each other. Yet they are not infrequently confounded, and it behooves us to study them accurately. A disease of the skin, gentlemen, is either the direct, immediate, positive result of the inoculation of syphilis, or, on the other hand, it is positively in no way connected with syphilis. There is no mysterious obscure course about the eruptions of syphilis: when they appear they are to be recognized as syphilis, just as a chancre is recognized as syphilis, and they constitute a definite group of symptoms. The various signs which the virus syphilis is capable of producing upon the skin are well-known and usually familiar forms, and they are to be regarded as the immediate result of the poison.

A word only concerning the treatment of our patient, which, with our views settled as to the diagnosis, is sufficiently simple and plain. Iodide of potassium in appropriate quantity is without question the remedy demanded. The patient will be

ordered ten grains, dissolved in a drachm of wine of iron, to be taken three times a day, about an hour after eating, and well diluted with water. If this quantity be not contra-indicated by any idiosyncrasy of the patient, as for instance by ptialism or coryza, it will be proper to allow him to continue this treatment for at least two or three months. But the length of time which a patient may take such a remedy will depend upon circumstances which may arise from time to time, and therefore no definite rule can be given. He should, however, take the medicine for several weeks, or longer, after all symptoms of disease have disappeared. The improvement in this case will probably not be rapid, owing to the extensive infiltration into the skin, and the squamous form which the disease has assumed, and which is always slow to disappear. With the exception of simple warm baths, which will be ordered, together with attention to cleanliness, the case does not require local treatment. We shall depend entirely upon our internal remedies.

[November 1, six weeks after date of lecture. The patient very greatly improved. The eruption has almost, if not entirely, disappeared from the scalp, and the patches upon the chest and abdomen are paler in color, and the induration very much less. He has been taking steadily the prescription ordered.—L. A. D.]

ORIGINAL COMMUNICATIONS.

THE CAUSES OF THE EXTENSION OF TYPHOID FEVER.

A Paper read before the Philadelphia County Medical Society, November 12, 1873.

BY DR. GEORGE HAMILTON.

MR. PRESIDENT, AND GENTLEMEN OF THE SOCIETY,—In compliance with the duty imposed upon me at the meeting held October 8, I offer as introductory to the discussion appointed for this evening a few remarks in relation to typhoid fever, having reference more especially to its causation and extension.

Most of those present have probably noticed in recent numbers of the medical journals reports of outbreaks of typhoid fever in various parts of Great Britain: of these, the one occurring in a certain district of London has most interested and occupied the attention of the medical profession, as its exciting cause seemed to have been clearly traced to the use of water or milk contaminated by the fecal discharges of patients affected with the disease. Cesspools, or drains connecting with them, are referred to as the chief sources of the vitiation of the water used. Uncovered vessels containing the milk alluded to had been kept (it is not stated how long) in the chamber of a man sick with typhoid fever, and this milk is believed to have been infected through absorption of the effluvia issuing from the skin, the lungs, or from the fecal dejections of the patient, as nearly all the persons to whom the milk had been sold were attacked by the fever.

* We shall have the pleasure shortly of laying before our readers a paper by Dr. Duhring giving the differential diagnosis between squamous syphiloderms and psoriasis.—*Ed. P. M. T.*

In the *Medical Times* of this city for September 27 will be found a statement from Dr. Murchison in regard to this matter, in which, as it appears, several members of his own family were, after using this milk, prostrated with fever. This account, and several others of nearly similar import, are doubtless candidly and fairly drawn out, and seem, at least, to rest upon a close observation of facts. In a paragraph of the *Times*, directly following the history of this outbreak of fever, the editor proposes, as worthy of discussion, this pertinent question: "Why, with our almost universal private cesspools, are we so exempt from epidemics of typhoid fever in Philadelphia? The disease is always with us, but anything like a spreading epidemic is a thing unheard of, at least in our experience."

Every intelligent, well-directed effort to determine the true source and mode of extension of this disease is worthy of commendation; and though such attempt, owing to the inherent difficulty of the subject, may be only partially successful, it nevertheless deserves the support of every one duly interested in the welfare of the community. That this matter needs, as the editor of the *Times* declares, investigation, is manifested in the diversity, and at times contrariety, of opinions still advanced in regard to the sources and modes of propagation of typhoid fever. Of those who have written upon the subject, a majority, probably, have had for their field of practice large cities and hospitals; and common observation has shown how difficult it is, in such positions, to arrive at a satisfactory solution of the question proposed. If the opportunities afforded in country and village practice were taken advantage of by the intelligent and observant practitioner in such favorable positions for observation, some definite conclusion might possibly be arrived at; for, as a rule, he is in such a relationship with nearly the entire population within the circle of his practice, as enables him to discover the situation and surroundings of the family in which the disease first appears. If the complaint spreads, as it sometimes does, to an extent and with a virulence and fatality hitherto unknown in this and many other cities, he may trace, as it were, from house to house, the direction the disease has taken, and the regular or interrupted movement that has marked its progress.

In consequence of the limited population and the isolation of the families, it is comparatively easy to ascertain if any opportunity for a contact of suspicious character may have occurred, the time, and the attending circumstances; whilst in vast and crowded populations continually in movement and nearly in contact, these points can seldom be satisfactorily established.

In regard to the origin of typhoid fever in the particular district in which the residence of Dr. Murchison is located, and from which his own family suffered, we may draw at least one practical lesson,—viz., if milk exposed—probably for no great length of time—to the atmosphere of a chamber in which a man affected with typhoid fever lies is susceptible of such alteration as to render it capable of engendering this disease, we may thence learn the necessity of guarding against risk of this

kind by enjoining upon those who may be in attendance as nurses to forbid children or others, who may gain access or be admitted to such room, to partake of milk so exposed, as is doubtless sometimes done even by adults, having no squeamishness and perhaps apprehending no danger from this source. A similar admonition is, perhaps, advisable in reference to all drinks and food, as some of these may be equally possessed of liability to vitiation from similar exposure.

The history of this outbreak of typhoid fever, in connection with that of some others occurring in various parts of England and Scotland, attributed in a number of cases to the use of water or milk poisoned through the medium of cesspools or sewers, will perhaps do much to strengthen the views of those who believe these to be the chief if not exclusive sources of typhoid fever, and efficient agents in its dissemination. Dr. Budd commits himself definitely to this view of the subject, and has, without doubt, many supporters; whilst a larger number, though conceding at times the influence of other agents, evidently regard the latter as of minor importance. A still greater proportion of writers and practitioners, especially those who have witnessed the violent epidemics that from time to time ravage the country, do not fully accept these restricted agencies as the dominant ones in their production, but are disposed to attribute them to some more general, more diffused influence, spontaneous in its origin, whose baleful effects they are acquainted with, but of whose nature and mode of action they are profoundly ignorant. Bretonneau has long since declared his belief in the contagious character of typhoid fever, an opinion in which probably only a small number of physicians coincided. Gendron, influenced, apparently, by what he had witnessed in regard to its development in the country, adopted the same view as Bretonneau, alleging as the cause of its greater and more rapid extension in rural districts the comparative small size of the chambers of the sick, and the more constant presence of the attendants in the room of the patient. He remarks that the sources of the first cases are frequently beyond our knowledge, even in isolated populations, and expresses the opinion that the disease is susceptible of transmission from fomites as well as by contact. Dr. Nathan Smith, one of the early most noted and experienced of American practitioners, declared himself in terms essentially similar. The vast majority of authors regard putrescent animal matter as the more usual source of typhoid fever, and some speak of it as being infectious and likewise contagious,—affecting the rich and the poor indiscriminately. Niemeyer expresses the opinion that spontaneous development of germs is an agency in the production of the disease, as well as that arising from cesspool contamination; also, that it may be of miasmatic or contagious origin; but that great difficulty exists in determining which of the two is the agent in crowded cities, where, owing to the great abundance of decomposing and putrescent animal substance, an unusual liability to the disease from either cause must be admitted. He alludes, in common with many other writers, to

the disposition to typhoid fever of persons recently arrived or having lived but a moderate length of time in places where the disease prevails. Physicians and nurses waiting upon those affected with the disease, he thinks, are seldom attacked. Flint admits the contagiousness of typhoid fever under certain circumstances. Spontaneous generation, however, probably evolved from putrescent animal and vegetable substances, he regards as the more general cause of the disease, but whether by the production of a specific poison, or as an auxiliary, is not satisfactorily determined.

A marked feature in the history of typhoid fever, noticed particularly by Drs. Nathan Smith and others, and that has given rise to much comment, is the erratic course it sometimes pursues, either in cities, or in the country, where it is more frequently noticed. In some seasons it will diffuse itself rather uniformly over a greater or smaller district, and, sooner or later disappearing from this, will reappear and diffuse itself over another tract near to the former, or at the distance of many miles, and at length revisit the place of its first appearance. Occasionally the disease is restricted to very narrow limits, and will, without diffusing itself, retire from this locality, to reappear, perhaps, at the distance of several miles, the intervening space escaping altogether. Dr. James Jackson speaks of the disease as sometimes appearing in a village or a single family, without leaving the precincts of either, when upon examination no appreciable cause for the attack could be discovered. In these instances he supposes its source to be some peculiar local condition of the soil, unconnected with filth or putrescence. This opinion, distinguished as the source whence it emanates is, will probably find little favor at present, when so many causes of a more definite and tangible character are adduced as the efficient agents in the production of typhoid fever.

My own experience and observation in the disease have been acquired in both country and city practice; and, whilst it may be said that the city is never entirely free from the malady, the same cannot be asserted in relation to the country. The complaint, however, once appearing in a rural section, is greatly disposed to spread and assume more or less an epidemic character; so that the number of persons attacked in proportion to population is correspondingly large. If typhoid fever, in my experience, once gained admission to the house of a farmer or his tenant, and the family were of the average number, as a rule it would not disappear from the premises until several persons had suffered an attack; whilst, on the contrary, my practice in this city, excluding one family where four persons were attacked, and two or three others in which two persons were affected with the disease, has given but a single case to each house. In the family of a wealthy farmer, consisting of eight individuals, all, except one, were affected,—six of them dangerously. The history of the disease as regards this family may, to those whose practice has been confined to the city, appear somewhat striking; yet it is nothing more than had from time to time been noticed by the country practitioner of that period, and doubt-

less since, where the complaint may have prevailed as an epidemic. A son of the farmer alluded to was the first to sicken, but not upon the premises. He had been absent from home for a number of weeks, at the distance of thirty-five or forty miles, and from thence he was removed, after the attack, to his father's residence. There was nothing in the location or the surroundings to account for the extension of the complaint to the remaining six members of the household,—the drainage from any suspicious matters being in an opposite direction to the supply of water for the family. In another farmer's family, of eight or nine persons, five were prostrated with typhoid fever. The mother was the first attacked; and she had been in almost constant attendance, by day and by night, at the bedside of a near relative suffering from the disease and living at the distance of several miles from the home of this mother.

It should perhaps be stated here that more than ten years elapsed from the time of my going to the country until my return to the city, and that during the first five or six years no cases of general fever were observed, other than those called bilious remittent. Yet for a season or two preceding the outbreak of typhoid fever some modification of the remittent form would arrest the attention of physicians. The first case of decided typhoid character occurred in the practice of a brother practitioner residing in my immediate vicinity. The house in which it appeared was situated near the Brandywine, about three miles below Chadd's Ford. As there had been no opportunity for contact of a suspicious character, and the local conditions were materially the same as they had been for an indefinite time, it was difficult to account for the peculiarities of this case, and it was therefore regarded as developed spontaneously through the agency of some general but indefinable influence. The disease gradually extended itself, though somewhat irregularly, during that season, and at the same time a more decided modification was noticed in the character of remittent fever, until at length its peculiar features were lost, or, as it were, supplanted by those of the typhoid form. The history of this first case, to whatever source it may have owed its existence, may be regarded as the prototype of other first cases, springing up in various sections of the country. In view of the fact that the condition of the farm-houses in general, and their respective local peculiarities, differed in no perceptible degree from those which had long characterized them, and in the absence of any known opportunity for contagious influence, the conclusion of the great body of country physicians of intelligence and observation was coincident,—that the outbreak was not referable to a perceptible specific cause, but was probably dependent upon atmospheric or telluric influences of exceptional character. For in this connection it must be remembered that the disease will sometimes, after having spread through a district for a season, again, in a year or two, reappear, and be nearly or quite as prevalent and virulent as before, the local conditions in the mean time remaining, so far as discernible, essentially the same.

It is, therefore, not surprising that Dr. James Jackson should have expressed the opinion that the disease might, under some circumstances, be indebted for its cause to a special local condition of the soil. The mutual actions and reactions of atmospheric and telluric elements, influenced as they doubtless are by changes in barometric, electric, thermometric, and hygrometric states, are absolutely unknown. To be able to assign to the operation of a palpable agent the origin of that class of diseases to which that under consideration belongs, is, indeed, a desideratum, for in this event we should perhaps have at command the means of cure, or, better still, of prevention. The attempt, however, of later years to attribute special poisons, received from without, as the causes of many diseases has, to a considerable degree, failed, partly for want of a sufficient number of pertinent and well-ascertained facts, and partly from attaching too little importance to the power of the organism itself to originate under certain circumstances elements of a deleterious nature, the product, generally, of abnormal physiology, in other cases the result, apparently, of physical or chemical action.

The views thus summarily expressed in reference to the origin and spread of typhoid fever are, as we think, nearly identical with those held by the majority of practitioners, and differ but little, if at all, from what is found in the writings of Drs. N. Smith, Bretonneau, Gendron, James Jackson, Flint, Bartlett, Niemeyer, and of many others of similar observation and experience.

Typhoid fever, as most of those present well know, has, for many years past, undergone an extraordinary modification. The allusion is to the comparatively small number of cases seen in the city, or in the older, more thickly-settled portions of the country, and to the greatly diminished mortality. The late Dr. W. W. Gerhard many years ago said to the writer that he no longer regarded typhoid fever as very dangerous, the change for the better in this city resembling what had long since been observed in Paris, where the mortality had, through a series of years, fallen from thirty-three to only five per centum, and this, too, without appreciable cause. The disease appears to be most prevalent and fatal for some years past in the smaller towns and villages situated in distant parts of the country, or in the less thickly-populated portions of the older States. The late Prof. J. K. Mitchell once informed me that nearly all the cases he saw were in the suburbs rather than in the central parts of the city, and this, we have reason to think, has been the experience of many other physicians.

The question, then, naturally arises, why typhoid fever should diffuse itself so much more extensively, rapidly, and fatally in the country than in this and many other cities. The opinion of Gendron, that in the country the more rapid extension of the disease through the family, and even beyond, might be attributed to the smaller size of the chambers and to the more constant attendance of the members of the family at the bedside of the patient, has, perhaps, some foundation, whilst it must be admitted that the malady is as frequently found in

the mansion of the farmer as in the cottage of the laborer. A widely-diffused, a sort of epidemic influence and contagion are evidently at work, just as we observe in several other acute affections in country neighborhoods, and to these chiefly are to be ascribed the frequency of attacks and their fatality.

The late Dr. Joseph Parrish used to remark in his summer course of lectures that in the consultations to which he had been called within a radius of eight or ten miles he had noticed that attacks of dysentery and remittent fever were beyond all comparison more numerous and fatal than he had ever witnessed in the families under his immediate care; and this is strictly in accordance with our own experience. The same observation holds good in relation to several other maladies, notably so in the instances of diphtheria and cerebro-spinal meningitis. Most of those whom I address can, doubtless, call to mind reports from various sections of Pennsylvania and New Jersey where in a single family four or five deaths had sometimes occurred from one or the other of these diseases; whilst this city, with its crowded population, passed through one or two epidemics of this kind with but a moderate number of deaths.

In view of these facts, with no appreciable local conditions to explain them, the inference seems inevitable that the greater proportionate number of cases and fatality of typhoid fever in rural districts are referable to a general dominant influence, unknown as to its nature or mode of operation, but perceptible enough in its effects. Whilst Dr. Budd and those who adopt his views are of opinion that the actual entrance into the stomach of water or other substances infected more or less indirectly by the fecal dejections of those suffering from typhoid fever is the general, if not exclusive, source of the disease, medical authorities commonly entertain the sentiment, as before stated, that to the decomposition and putrescence of animal and vegetable matter in general are we to attribute the origin of the malady. Whether the effluvia arising from putrescent substances become a cause of typhoid fever by being received into the stomach, through direct or indirect means, as some suppose, or from absorption by the mucous membrane of the lungs, as others believe, and whether the person suffering from the malady becomes himself a source of the disease to others exposed to inhaling the effluvia emanating from the surface of his body or lungs, or from his fecal discharges, are points more or less connected with the proposition for examination. The real purport of the question was to invite discussion regarding the singular fact that the city, honeycombed by cesspools (as the editor of the *Medical Times* rather facetiously says), is so generally exempt from any violent outbreak of typhoid fever. From what has been said, it is clear the question need not be restricted to such narrow limits; for, independently of cesspool vitiation, there are in the city innumerable sources of putrescence that either exist not at all or to a very slight extent in the country. The bone-boiling and fat-melting establishments, the soap- and glue-factories, the places for the reception and utili-

zation of dead horses, cows, and other domestic animals, the sites for the deposit of night-soil, ill-conditioned slaughter-houses, with their appendages in the shape of wells, pits, sinks, and connecting drains, the close, dark, confined cellars serving as adjuncts to inferior provision-stores, sometimes reeking with the exhalations of putrescent animal and vegetable matter, and, in addition, the numerous cellars and back yards of the poor, improvident, and degraded, where the eye and the sense of smell are alike offended and disgusted.

It is, then, not surprising that Niemeyer and many other writers have declared that the elements of typhoid fever abound to an extraordinary extent in large and crowded cities.

The question proposed is thus rendered more pertinent, and apparently more embarrassing and difficult of solution; yet a single fact, before alluded to, that strangers entering into or persons having lived but a moderate length of time in cities or towns where the disease exists are especially disposed to be attacked, may perhaps justify the supposition that the germs of the malady are, to the permanent population, rendered nearly innocuous, from a sort of power of accommodation or resistance, on the part of the economy, to a nearly always present noxious agent, of variable yet for the most part not great intensity. But a truce to theory.

In the recent International Medical Congress held at Vienna, an interesting report of which is to be found in late numbers of the *Medical Times* of this city, Prof. Hebra, one of the Vice-Presidents, said, in relation to the duties of delegates to that body, that "learned discussion of theoretical points was not wanted, but rather the promulgation of the results of observation made from the proper objective point of view." Impressed with the justness and value of this remark, and conscious that the question before you for examination this evening can alone be solved, or in some degree advanced, by pursuing the path just indicated, I refrain from further trespass upon your time, well convinced that verbal discussion, affording as it does to each member opportunity to relate that which he has had under actual observation, must result in eliciting a greater number of important facts and pertinent observations in regard to the subject in hand than could be expected in a short paper relating briefly the experience of an individual, or giving expression to such facts and observations as casually occur or might be cited from a cursory and an imperfect examination of authorities.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. T. G. MORTON, NOVEMBER, 1873.

Reported by Dr. D. DAVIDSON.

CASE I.—POPLITEAL ANEURISM—CURED BY FLEXION.

W. H., a miner, aged 26, was admitted October 23. Five weeks ago this patient had his left leg caught in the wheels of a truck which he was pulling,

and a severe twist of the knee was the result. He was able to continue at work for a day or so afterwards, but great swelling, pain, and stiffness of the knee and limb soon followed. On examination we find a painful, rather dense, pulsating, and movable tumor, about as large as a chicken's egg, in the popliteal region. Pressure on the femoral artery controls the pulsation, and decided pressure on the tumor produces the same result. There is no pulsation in the anterior or posterior tibial arteries, and the temperature of the limb is four degrees lower than that of the other side. The diagnosis of the case is, that a rupture of the artery has occurred, and has been quickly followed by the formation of a tumor, and also of a clot which has doubtless extended into the artery, obstructing the flow of blood through the limb so that circulation in the femoral exists only as far as the tumor. There has been a gradual absorption of the extravasated blood in the popliteal space, and by the collateral circulation the limb is nourished. Since pressure on the tumor entirely controls the pulsation, flexion of the limb will doubtless effect a cure. A pad of lint was applied to the aneurism, and the limb was firmly flexed upon the thigh, and retained in this position by a bandage which encircled the patient's waist.

November 8.—The apparatus was removed, and the tumor was without any pulsation, and much reduced in size.

November 26.—The patient was discharged cured.

CASE II.—SUSPECTED CALCULUS IN THE URETER—DIRECT EXAMINATION OF THE URETERS.

There has been a case in the hospital for some time past the diagnosis of which has been somewhat obscure, and which has been cleared up by a comparatively novel operation, which in doubtful cases may prove of considerable value.

This patient, a jeweller, aged 26, in the month of August last, was seized in the right iliac region with intense pain, which at first was constant, but afterwards intermittent: it was always referred to the same locality. The suffering has been at times so great that large doses of morphia hypodermically have failed to give relief, and the patient has been kept often for hours under the influence of ether. Obstinate constipation of the bowels, with pain in the iliac region, and suppression of urine, without fever or any gastric disturbance, have been the prominent symptoms. The most active purgatives and enormous enemata have failed to produce any action of the bowels, except at long intervals, and then the discharges have been very slight.

The abdomen on examination did not at any time show the least swelling or evidence of inflammation; the right iliac region was very sensitive, and deep pressure produced intense pain. An enlargement, which was apparently the seat of the trouble and was about the size of a pigeon's egg, could be felt deeply situated. A finger passed into the rectum did not reach the enlargement. Whether the mass was a calculus in the ureter, or some impaction of the bowel, or tumor pressing on the ureter, was not determined.

November 21.—The bowels were well cleaned by a large dose of oil, followed by a stimulating enema, as it was determined to explore the rectum by the introduction of the entire hand into the gut.

After complete anæsthesia, Dr. Morton gradually dilated the anus with the fingers of the right hand; the parts quickly yielded, and the hand and forearm were readily carried into the bowel. The line of the ureter and the region of the kidney were found normal; the aorta and iliac vessels were readily distinguished, and it was definitely ascertained that no calculus existed, and that the pain was either simply neuralgic, or was dependent upon a mass of hardened feces, which came

away just before the etherization. The patient had no control over the bowel for two or three days after the operation, but on the fifth day the sphincter resumed entire control over the anus. Several large stools were passed directly after the examination.

November 27.—Patient discharged quite well.

In many cases of doubtful diagnosis in abdominal tumors, aneurism, etc., this method of rectal examination might be of great value, while we have exhibited in this case the wonderful dilatability of the rectum without any ill effect upon the sphincters.

ILLUSTRATIONS OF LEPRO TUBERCULOSA OR GREEK LEPROSY.

Through the kindness of Joseph G. Rosengarten, Esq., of this city, I am enabled to show you several photographs illustrating the Greek elephantiasis,—lepra tuberculosa; a leprosy, so called, which has lately occurred at Honolulu.

Mr. Lawrence McCully, resident at Honolulu, writes, "The system of the government has been to gather all cases, known or suspected, into a temporary receiving hospital, near Honolulu, there to be examined by the surgeon in charge, and if doubtful, or if appeal to others is made, then by other surgeons of the city. The pronounced lepers are then sent off to the leper settlement on the island of Molokai (at this date one of the smallest of the Sandwich Islands, and lying south of Honolulu). The work has been finished; there are none now in the receiving hospital; and I am assured by the chief agent of the Board of Health that there are now no lepers abroad who may be brought in. We can only wish and hope that he is quite correct, and that no more will develop.

"The settlement at Molokai, in the first place, is isolated by law for the residence of the lepers.

"From the leper settlement, the following extracts from a letter of recent date received from Mr. William P. Ragsdale, at Kalawao, will be read with interest:

"I am happy to inform you that the lepers are well taken care of. The majority of the afflicted have better homes, and more and better food than they were able to get at their own homes,—wholesome food. No pains nor expense have been spared to give comfort to the poor leper. I am at present engaged in laying water-pipes from the Kalawas (not Kalawao) gulch to the leper hospital, about one and a quarter miles; will finish this job up in about one week's time. This will be a very great help to the poor lepers (who have had heretofore to carry their water on their backs, and on the backs of their animals), and assist them in keeping clean their bodies. They have got plenty of land to cultivate, if they are inclined that way: very few of them indeed have shown any desire for mahiai (cultivating). The total number of lepers at this settlement is seven hundred and ninety-seven: forty-five are school-children, three foreigners, and some five or six Chinamen. There are fifty-seven who are cared for in the hospital ward and fed by the cook; twenty-nine live in the cottages on the hospital premises. The sick in the hospital are looked after in the best manner; they have everything to eat that they may have any wish for. Mr. William Williamson is the purveyor of the hospital, and he takes very good care of the sick, as far as I have been able to see; and the cleanliness of the patients is more carefully looked after than formerly."—*Advertiser*, October, 1873.

"The writer, Ragsdale, a leper, is a half Hawaiian; the Williamson mentioned is an Englishman, with a native wife and family; is himself a leper, and all the family lepers."

The disease appears to be looked upon as *contagious* and generally incurable. Prof. George B. Wood states this: "The part most frequently affected is the

face: knotty, irregular prominences are exhibited here and there over its surface, separated often by deep furrows. The skin is much hypertrophied and rugous upon the cheeks, forehead, and chin; the lips, ears, and alæ of the nose are enormously thickened; the nostrils are distended and the brows overhanging; the eyebrows, eyelashes, and beard have fallen off, and the whole face is enlarged, uneven, oily, and of a peculiar dusky hue.

When a limb is invaded, the subcutaneous tissue often swells, the tumors are thickened and discolored, and the part affected becomes greatly deformed.

WILLS OPHTHALMIC HOSPITAL.

SERVICE OF GEORGE C. HARLAN, M.D.

Reported by W. H. WINSLOW, M.D.

ASTHENOPIA—ACCOMMODATIVE AND MUSCULAR. HYPERMETROPIA.

J. L., a healthy woman, æt. 20 years, a domestic, first noticed a weakness of vision three years since, which had continued up to the time of her application for relief. There was much intra-ocular and supra-orbital pain, accompanied by frontal headache, which latter increased in severity whenever she used her eyes in bright light. Sometimes, during paroxysms of pain, she lost her sight completely for a short period, which probably occurred from paralysis of the accommodation. At such times the eyes became injected and hot, and the tears would flow freely, covering the blurred and indistinct impressions of the printed page. After rest for several days, all these symptoms would disappear, only to be renewed by use of the organs in near vision. The patient was really very uncomfortable and much distressed for fear she would ultimately lose her sight entirely. She stated that she suffered much pelvic pain during menstruation, and occasionally had temporary loss of power in the arms, probably a form of hysterical paralysis.

The eyes and appendages proved to be perfectly healthy in appearance and action. In the right $V = \frac{20}{L}$ Snellen, and in the left $\frac{20}{XL}$, but with a $+1\frac{1}{8}$ glass it rose to $\frac{20}{XX}$ in this eye.

Ophthalmoscopic examination showed the fundi normal, but detected a very high degree of hypermetropia.

After paralysis of the accommodation by atropia, there was found a hypermetropia in the right eye of $\frac{1}{2}$, and in the left $\frac{1}{4}$. She was ordered glasses of $+1\frac{1}{8}$, which improved her vision much and entirely relieved the distressing symptoms above enumerated.

The full correction was deferred to a future time, as she had very little near work to do, and could not relax her accommodation enough to see distinctly at a distance through stronger glasses. She was also ordered the elixir of iron, quinine, and strychnia, as her general health was a little below par.

TWO CASES OF ASTIGMATISM.

A. D., a school-girl, æt. 13 years, was not able to attend to her studies regularly, on account of weakness of her eyes.

Whenever she attempted to read or sew she suffered pain in the eyes, the sight became blurred, and severe frontal headache supervened, which continued for hours afterwards. There was also at such times a decided convergent strabismus of the left eye.

Examination after atropia had paralyzed the accommodation detected in the right eye a hypermetropia of $\frac{1}{2}$ in one principal meridian, and of $\frac{1}{8}$ in the other; and in the left eye of $\frac{1}{2}$ in one meridian and $\frac{1}{8}$ in the other.

She was ordered for the right eye a $+1\frac{1}{2}$ spherical, combined with a $+2\frac{1}{4}$ cylindrical, with its axis at 60° ; and for the left a $+1\frac{1}{4}$ spherical, combined with a $+1\frac{1}{8}$ cylindrical, with its axis at 120° . The glasses completely corrected the strabismus, and entirely relieved the asthenopia.

A. B., a healthy man, æt. 25 years, had been suffering with "weak" eyes six or seven years. Any continued use of them in reading or writing had been followed by fatigue and a burning sensation in the eyes, and sometimes by frontal headache and dizziness.

He had frequently been obliged to discontinue the use of his eyes for near work for weeks at a time. Having lately attempted to use them more than usual, each attempt had been followed by a confusion of vision and dizziness that continued for hours to such an extent as to be a source of great annoyance and distress as he walked the street. This, of course, occasioned anxiety, and had a decided effect upon his health and spirits.

Vision varied very much with the state of his health and strength, and with the fatigue or rest of his eyes.

At the time of examination $V = \frac{15}{LXXX}$. A weak convex glass ($+8\frac{1}{6}$) made distant vision worse, while a $-3\frac{1}{6}$ increased it to $\frac{15}{XL}$, just double.

Suspecting hypermetropia with spasm of the accommodation, the accommodation was paralyzed by atropia. It was then found that there was a hypermetropia of $\frac{3}{8}$ in one principal meridian, and of $\frac{1}{8}$ in the other.

A spherical $+3\frac{1}{6}$ combined with a cylindrical $+1\frac{1}{8}$ with its axis at 75° gave a distant vision of almost $\frac{20}{XX}$ Snellen, and relieved the asthenopia.

INSUFFICIENCY OF INTERNAL RECTI.

E. M. N., a woman, æt. 33 years, complained of disturbed vision, intra-ocular and supra-orbital pain, lachrymation, and general discomfort in the eyes. She said the trouble commenced four months previously, after a miscarriage, in which she had lost much blood. She had never been able to read or sew for any length of time since. She could read only a few minutes at a time, when the letters would run into each other and the page become blurred. Every attempt to use the eyes was followed by pain in the eyes, and headache.

The external appearance of the eyes was natural, and the ophthalmoscope revealed no interior disease. Distant vision was normal, $\frac{20}{XX}$ Snellen. There was no error of refraction, and the power of accommodation was unimpaired.

With vertical diplopia, there was a horizontal separation of images, which it required a prism of 8° , base inwards, to overcome. Prismatic glasses of four degrees each entirely relieved the asthenopia.

She was directed to use them only when obliged to occupy herself with near work, and the elixir of quinine, iron, and strychnia was prescribed.

INSUFFICIENCY OF THE INFERIOR RECTUS.

K. J., a healthy man, æt. 47 years, a clerk by occupation, doing much writing, noticed a blurring of objects, two months since, which continued and increased. There were no symptoms of any constitutional cachexiæ, and he had generally enjoyed good health; but, owing to financial reverses, he had suffered much mental inquietude. When writing on a line, it would seem to move upwards into the body of the manuscript and become lost. In looking at a picture, the title below would become displaced into the details of the cut. When he met a gentleman in the street, there seemed to be two, one taller and behind the other, and

in looking at his face the shirt-collar would appear around the face just below the eyes. He always had to step over two curb-stones.

In reading print, the letters, though at first clear for a few seconds, became blurred, and he lost his place. Looking at a distant light, he saw one image alone, but when a red glass was placed before one eye there were two distinct images, one being red, separated vertically about a foot. When the red glass was before the right eye, the red image was below and slightly inclined to the right. When before the left, it was above and slightly inclined to the left of the vertical meridian.

A prism of 6° , base downwards, before the right eye, or base upwards, before the left eye, fused the images. A pencil held horizontally about 18" in front of the eyes was seen singly except when carried towards the lower margin of the field of vision, when the images were separated vertically. When he looked at a black dot with a vertical line drawn through it, it appeared at first as one, if the eyes were not previously fatigued. After looking at it steadily a few seconds, one image remained stationary, and another moved up the line, the line being prolonged, but remaining single.

A prism of 5° , base downwards, before the right eye, brought the two dots together, affording only one image. When the colored glass was placed before one eye, a prism of 6° was required to fuse the images.

The vertical diplopia showed that either the superior or inferior rectus of one of the eyes was at fault. The greater tendency to diplopia at the lower part of the field of vision limited the disease to one of the inferior recti, and the fact that the image of the right eye was found to be below that of the left fixed it upon the inferior rectus of the former.

He was ordered a prismatic glass of 3° for each eye, base downwards on the left side, and base upwards on the right. The glasses, which gave complete relief from all the symptoms, were ordered to be worn only occasionally, while he was directed to come to the hospital three times a week, to have the induced current applied to the weakened muscle.

FEIGNED DEATH—RECOGNITION BY FARADIZATION.—Professor Rosenthal, of Vienna, has recorded an interesting case of trance detected by faradization in a hysterical woman whose death had already been certified by a country practitioner. It had been found that a looking-glass held to the mouth of the woman did not show any moisture, and that melted sealing-wax dropped on the skin caused no reflex movements. Rosenthal, who was accidentally present, found the skin pale and cold, the pupils contracted and insensible to light, the upper and lower extremities relaxed, the heart's impulse and the radial pulse imperceptible. Auscultation, however, showed a feeble, dull, and intermittent sound in the cardiac region. No respiratory murmurs were audible. All the muscles of the face and the extremities responded well to the faradic current. Although the patient had been apparently dead for thirty-two hours, he thereupon informed the relations that she was only in a trance, and recommended that attempts at resuscitation should be perseveringly followed. On the following day he received a telegram saying that the woman awoke spontaneously twelve hours after his visit, and gradually recovered her speech and movements. Four months afterwards the patient called upon him, and informed him that she knew nothing of the commencement of the attack of lethargy in which she had been; that she had afterwards heard the people about her talk of her death, but had been utterly unable to give the slightest sign of life. Two years afterwards, she was still alive and tolerably well.—*British Medical Journal*.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, DECEMBER 20, 1873.

EDITORIAL.

THE MEDICAL CORPS OF THE ARMY.

OF all devilish inventions which the mind of man has sought out, or which the circumstances of life have brought forth, war is simply the most devilish,—turning wealth and comfort into ruin and misery, happiness into blank despair, life into death, and, but too often, man into a fiend, Contravening every law of morality, contradicting every practice of Christianity, it stands the one great monument of man's depravity. Yet it is the basis of modern civilization, the strength of government, the majesty of the law, the very groundwork of Christianity; offering the awful paradox of peace and good will to man resting upon the field of carnage and the place of strife. As Christianity deepens in the hearts of men, as it becomes more and more universal, so, undoubtedly, will war become less and less frequent, until, in the millennium morning, peace and good will shall reign triumphant. Until then, however, we can only lessen the frequency of war and mitigate its horrors.

Probably the world over it will be acknowledged that our country—the United States of America—has done as much as or more than any other nation in both of these directions. The Geneva arbitration, the quiet waiting of the Executive in our troubles with Spain, are recent and most gratifying proofs of the decay of the war-spirit among us. Yet war, as has been said, is an inevitable heritage of man, and the nation that eschews physical force must see the evil triumph over the good, the commune over religion, anarchy over order.

Knowing, therefore, that wars and fightings must come, it is well that we mitigate, as far as may be, their distresses. During our late rebellion those gigantic philanthropies, the Sanitary and the Christian Commissions, taught the world new lessons of charity; but the relief they afforded upon battle-field and in hospital was as nothing when compared with that given by the regularly organized medical corps of the army. Let private charity do what it can; after all, it can only aid and supplement what must ever remain the great relieving agent in the time of war,—the medical department of the army. How important is it, then, that the medical corps should be maintained at the highest possible efficiency, organized in the most thorough manner, its *esprit de corps* raised by the strictest discipline, its *personnel*, which in it is everything, sustained by fresh drafts from the best young talent of the country and by those rewards which are the incentives to continuous labor!

As every one knows, the organization of our army during war is an anomalous one, the so-called "regular army"—the standing army of the country—affording merely a nucleus around which gathers a mighty host—the "volunteers." It is very evident that the latter must be composed of men recently civilians, and that its surgeons must be physicians who are novices in military surgery and the various especial departments of medical science relating to war. Hence it is all-important to maintain at all times a very large "regular" staff,—a body of men drilled in all the requirements of army life, who shall guide, direct, and leaven the general mass in war-time. Doubly important does this seem when the confusion of suddenly organizing large armies, the difficulties of selecting among unknown and untried men those fit for responsible positions, are borne in mind. The superiority of the regular over the volunteer staff is a necessary result of the same laws that render professionals superior to amateurs in any rôle of life,—a result which was very apparent in the last war, when the largest hospitals were commanded by assistant-surgeons of the regular army,—lieutenants in rank and pay ruling twelve or fifteen hundred men,—the stripling holding the command of a colonel. We have neither space nor desire to re-echo the plaudits which the world has long offered to our medical department since its work has been known. Simply let us say that its achievements exceed anything of the sort the world over; and let us in justice add that those achievements had their inspiration, their source, in the staff of the regular army.

Again, as is well known, the effective strength of

an army, the measure of its real power, is often very different from its numerical strength on paper. In keeping men *out* of the hospital the medical corps ought to be of more service to the government than in treating the soldiers in the hospital. The American soldier probably costs more to get into the field than the soldier of any other nation, and it is therefore doubly imperative upon the government to take care of him. It cannot afford to neglect him. Disease is an infinitely more dangerous foe than the cannon-ball and the rifle-bullet, but one that can be to a greater extent guarded against. Any person in the habit of reading the English medical papers will see how this is recognized abroad. Week after week the editorial columns are filled with discussions of the proper methods of meeting the medical difficulties of the Ashantee War, soldiers and civilians consulting together concerning what is said to be "a doctors' and an engineers' war."

It is evident that the preventive treatment of disease in the army involves manifold questions entirely unconnected with civil life; that army hygiene is distinct from civil hygiene; that it is an imperative necessity to maintain a large body of highly-educated, able men who shall devote themselves to the study of the various military medical problems with the steady energy that a man puts into his life-work.

The maintenance of the medical corps of the regular army in the highest possible efficiency is therefore but the dictate of common sense. Yet, some time since the rebellion, Congress, moved by that spirit of penury which loses sight of the distant gold eagle by looking at the penny close at hand, stopped all promotions and stopped all appointments to the medical staff; at one fell blow taking away every inducement of those in the army to stay there, and shutting the door against any who might be attracted by the barren pasturage left. It was well they did both, however. If they had only stopped promotion, the service might have been filled up by the merest incompetents, the best men staying out because they saw no sufficient attraction ahead. It was fortunate, then, that the door was shut, so that to-day there are sixty-four vacancies, even though the government has become a trader in medical services, buying temporary services at temporary prices of any one who can offer them.

We might write at length of the real injustice of shutting off promotion. We might tell of men who had abandoned lucrative positions and sure promotion in civil life, and made settled permanent contracts, because they were needed by their country,—contracts into which entered as an integrant

part the chances of promotion. We might contrast the achievements of the last war and the death-roll—*greater* than that of any *other staff corps* of the army—with the contumely of the present, did not justice seem dead,—did we not believe that any body of men who could have passed the original law simply were devoid of any sense of justice, since the act was a direct *repudiation* of the agreement of the government with those who entered the army. Surely, however, a sense of right still exists among the American people, if not in their representative body; and surely that people, though slow to move, will eventually see that their representatives do right. As we have already said, we do not ask Congress to repeal the present law on the ground of justice, but, in the name of a people over which the war-cloud has scarcely passed, we demand it as a necessity. When war shall come, shall our citizen soldiery die on the battle-fields, in imperfectly provided and governed hospitals, because our country was too poor—nay, rather because Congress was too stingy—to afford the necessary pittance in time of peace? Shall our government continue to huckster in medical services for present wants, buying those so needy, so hopeless, that for a present pittance they will barter all chance of future reward? We trust not. Let every civil physician in the land use his influence in securing the repeal of the bill as asked for by the American Medical Association, and surely even an obstinate Congress—which we trust the present will not prove—will yield to justice, expediency, and the will of the people.

AS is well known, in the "olden time" advertising by the profession was done more freely than at more recent periods. We are indebted to Mr. Malin, the gentlemanly steward of the Pennsylvania Hospital, for the following extract from Poulson's *American Daily Observer*, 1806. The patient alluded to was admitted to the Hospital December 1, 1806, and, on recovering, left the institution April 22, 1807.

"PENNSYLVANIA HOSPITAL, December 27.

"On Wednesday, the 25th instant, a WEN was extracted by Dr. Physick, in the circular room, from the cheek and neck of James Hayes of Dauphin County, in the State of Pennsylvania, in the presence of Doctors Wistar and Cox, Physicians of the Hospital, and about 80 students of medicine from different parts of the Union, who were privileged to attend the practice of the house. This wen had been upwards of twenty years progressing in its growth, and, when extracted, it was measured and weighed.

"The dimensions were as follows:

"Projection from his cheek 7½ inches.

"Circumference round the base 23 do.

"Do. in its largest extent 25½ do.

"Do. in the least part of it 19½ do.

"The weight was seven pounds.

"It is supposed the patient might have lost about ten or twelve ounces of blood. This severe operation he bore with the greatest fortitude, and there is a reasonable prospect of his doing well."

IN a recent number of the London *Lancet* is an editorial upon the subject of International Copyright Law, in which occurs the following passage, which we would commend to the business consciences of some well-known publishers if we thought they had any:

"The reproduction of British works in the United States is of course nothing less than piracy (however disagreeable the word), and the Americans have hitherto stoutly resisted all attempts by both English and American authors to bring about some mutual good understanding."

We say Amen to this. As the *Lancet* afterwards intimates, however, it is not the "Americans," but a ring of publishers, who, strong in their ill-gotten wealth, simply grow stronger day by day through the half- or not-at-all required toil of authors.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held at the hall of the College of Physicians, November 12, 1873, at 8 o'clock P.M.,

Dr. W. B. ATKINSON, PRESIDENT, in the chair.

The paper of Dr. G. HAMILTON (see page 178) was read, and gave rise to the following discussion:

Dr. WM. GOODELL agreed with the author of this admirable paper in the opinion that the virulence and contagiousness of typhoid fever in country towns and villages are in a great measure attributable to the greater impressibility of countrymen. They certainly are not, as suggested by Gendron, owing to small rooms and to the congregation of the whole family in them. For the poor of large cities are, in these and other hygienic respects, far worse off; and yet this disease rarely attacks more than one member of a citizen's family. The peculiar vulnerability of countrymen to miasmatic and contagious influences is well known. It has long been remarked by military surgeons that the raw but healthy recruits from country towns sooner succumb to the diseases and the hardships of a campaign than the pale and unhealthy-looking lads drafted from the shops of a great city. People born and bred in the courts of a city never breathe pure air, and are daily and hourly exposed to morbid influences, which they resist, but which would soon cut short the life of a countryman. Thus it is that in epidemics acclimatized citizens escape, while the recent resident early falls a victim. In this sense there are grains of truth lying

at the bottom of the legend that Mithridates had so accustomed his stomach to violent drugs that there was no poisoning him.

Dr. HAMILTON thought the hazard was much greater on the part of the city, as regards the condition of the privies in reference to their possible or probable agency in the production of typhoid fever. In many places west of Broad Street the privies, if not connected with a sewer, were nearly always full, evidently from some peculiarity of soil permitting the wells to fill rapidly with water, the fæcal substance resting generally upon the surface.

Dr. ESHLEMAN thought that cesspools were generally kept in a worse condition in the country than in the city, and that the disease was more fatal in the country. He had never in the city met with a second case in the same family, or in the vicinity. He regards it in our city, however grave the symptoms, as very amenable to treatment. He relies principally on efficient supporting remedies. He uses two to six pints of milk daily, besides beef-tea, wine, eggs, and brandy in their turn.

Dr. GOODELL asked Dr. ESHLEMAN to describe the cesspools in the country.

Dr. ESHLEMAN, in reply, said the wells were usually of a large size, from four to eight feet deep, and neatly housed. But their contents were very seldom removed or disinfected. He seldom entered them, because of their very offensive odor. He thought it strange that the disease was not more prevalent if human excreta were the source of its origin. He would add that, in seeking the origin of a case which he has at this time under treatment, he discovered that eight days prior to his taking charge of the case, and one day before prodromic symptoms set in, his patient had been exposed to exhalations of a most offensive character, that arose from the emptying of a cesspool in the yard, and which they inhaled during the night and while removing their household goods the next day.

Dr. COHEN inquired what was the drainage of small towns in Dr. HAMILTON's experience.

Dr. HAMILTON, in reply, said that the village in which he formerly resided was finely situated upon the ridge dividing the Brandywine and Red Clay Creek. He had never noticed any condition of the surface that would be likely to furnish miasmata or effluvia capable of engendering disease; though the population, many years previous to his residence there, was more than decimated by dysentery. The cases of typhoid fever were not frequent in the village.

Dr. B. LEE said that he found himself entirely unable to agree with the remark of the author of the paper, that it might have been of a more practical character. He considered no questions more truly practical than those relating to the prevention of disease, and that not until the profession gave a due amount of attention to these questions would it rise to its full dignity and fully discharge its obligations to society. Of the many interesting topics suggested by the paper, he would refer to a few only. As regards the existence of a certain impalpable, undefined, and as yet not understood condition of the soil, as a cause of typhoid fever, he would instance a circumstance which appeared to him to have a very direct bearing upon it. In the neighboring city of Wilmington, about twenty-seven years ago, an epidemic of this disease made its appearance, which was of an unusually fatal character, attacking rich and poor alike, and carrying off many of the most prominent citizens. Shortly before its commencement, the main street of the city had been upturned nearly its whole length (about a mile), for the purpose of introducing new water-mains. The excavations were at least six feet in depth, and remained open for one or two months. No other cause for the outbreak could be assigned, and the physicians of the town were unanimous in ascribing

ing it to this. The disease had never before or after prevailed there as a decided epidemic. In regard to the greater frequency of the disease in its epidemic form, and its greater virulence in the country than in the city, it should be remembered that in the city, however filthy the condition of our cesspools might be, our water-supply was drawn from a distance, and was therefore entirely free from all suspicion of contamination by our own excreta at least; while in the country sufficient pains were not taken to avoid the possibility of drainage from the cesspool into the well, a danger which was especially great in porous soils or where the rock strata dipped towards the latter from the former.

The writer had alluded to infected milk as a source of typhoid fever. This he considered a matter of the deepest moment, and one worthy of close investigation. Milk is a fluid so highly vitalized, so near akin to blood itself, especially when warm from the cow, the condition in which it would be exposed to emanations from diseased persons or infected utensils on the dairy farm, that it formed a most fitting nidus for the reception and development of disease-germs. He desired to ask the author of the paper, as having had opportunities of observing the disease in the country, whether he had ever noticed any relation in point of time between the ploughing-season and outbreaks of the disease in question, as that might throw some light on the theory that the exposure of the soil was capable of producing it.

Dr. HAMILTON stated that the account given by Dr. LEE of an outbreak of typhoid fever of unusual extent and fatality in the city of Wilmington, Delaware, the origin of which was supposed by many to have been the exposure to the atmosphere of a large amount of fresh soil, reminded him of a similar outbreak in Germantown. He had visited in consultation on that occasion a young man in a family where two or three others were affected. He was informed that many other cases existed in that particular portion of the town, and that no explanatory cause presented, unless it might be found in the fact that the cutting down of a hill in grading a street had exposed to the action of the atmosphere and light a very great quantity of fresh earth. Dr. H. had seen nothing to induce him to suppose that freshly-ploughed ground might have an influence in giving rise to typhoid fever.

Dr. G. KERR mentioned an outbreak that occurred in one of the normal schools of the State in the year 1859. Over two hundred young ladies were in attendance. About forty-five were taken with the fever, and a large number of the cases proved fatal. The cases were taken from the school (in which building they also boarded) to their respective homes.

It was noticed at the time that the delicate-looking girls from the city did not seem to be affected at all, whilst the strong, hearty, robust country girls were the sufferers. In one family to which a patient was taken, three more of its members took the same disease, and all four died. Every care was taken to prevent contagion. In this case the house was elevated, thoroughly cleansed, and the members of the family were not permitted to enter the room.

Dr. Kerr's own sister was among the number that took the disease, and was very ill. The entire family was almost constantly exposed in the sick-room. The usual care for ventilation and cleanliness was taken, and no one of their family suffered in the slightest.

The cause of the disease was attributed to the leaking of a pipe leading from the water-closet in one of the upper stories. He did not believe that the turning over of the soil or ploughing has any connection with the disease whatever. He thought that if the effluvium of privies had anything to do with it, the malady would be exceedingly common in this city, where hundreds of the houses are as bad as the privies themselves.

The fact that those who clean sewers are not subject to the disease was proof that this cause had nothing to do with it. Or else, if so, as some affirm, then these persons must have become acclimated, so to speak, to such an atmosphere. He thought perhaps this might be the reason we do not suffer more in cities.

Dr. ATKINSON stated that he very rarely saw any typhoid fever on the "Neck," in the lower part of the city, although the night-soil was spread over the ground in great abundance and in the immediate vicinity of their dwellings. During the epidemic of smallpox there was none among the "Neckers."

Dr. BALDWIN asked Dr. ATKINSON as to the character of the drinking-water in that locality.

Dr. ATKINSON replied that the water was obtained from shallow wells, but did not think there was anything deleterious in it. The soil is diked.

Dr. BURNS said that in his neighborhood, five miles north of Philadelphia, is a large manufacturing town, the greater portion of which is on elevated ground, the Tacony Creek bordering it on the southwest. Here, for the last thirty-five years, he had treated many cases of typhoid fever; at sundry periods there have been epidemics of this disease. In 1865 there were a number of cases in a salubrious part of the town, in two adjoining houses. He attended seven patients in the one and four in the other, all with a grave form of the disease, and all recovered. In the vicinity there were a number of others under the care of neighboring physicians. In endeavoring to investigate the cause or causes of this visitation, Dr. BURNS thought it proceeded from clearing out an old mill-race, the mud of which, being thrown upon its banks, sent forth noxious effluvia, the dwellings being only about fifty yards distant.

At another and later period, there were three cases in a well-appointed farm-house, where no deleterious cause appeared to exist. In this case he thought the morbid influence might have arisen from the storing away of vegetable matter in the cellar, which is very common in farm-houses. He thought the supply of drinking-water was always worthy of consideration, and that there was danger of contamination if the cloacæ were in close proximity. It is difficult to ascertain the cause of this and any other disease. Doubtless there are special causes, and there may be atmospheric and telluric influences, with modifications due to electricity, which have powerful effects in the production of disease. Moreover, the constitution, habits, food, and clothing of the patient have each their share as factors of morbid action.

Dr. F. J. BUCK thought that where intermittent fever was prevalent, as on the Neck, there typhoid fever was not to be found. This he thought might be owing to the congested spleen acting as a revulsive. He thought he had observed an antagonism between the two diseases.

REVIEWS AND BOOK NOTICES.

THE STUDENT'S GUIDE TO MEDICAL DIAGNOSIS. By SAMUEL FENWICK, M.D., F.R.C.P., Assistant Physician to the London Hospital. From the Third Revised and Enlarged English Edition. With Eighty-four Illustrations on Wood. Philadelphia, Henry C. Lea, 1873, pp. 328.

This is a good book, and one which has been well received in its native city, as is proved by the fact that it has so soon attained the honors of a third edition; and yet we regret to find in its prosperity a sure evidence that the average British medical student is as fond of aids to superficial knowledge as his much-commiserated American brother, and seizes with equal avidity upon

"Compendis" which hold out the oft-repeated but always delusive promise of guiding him upon a royal road to learning.

Especially should this encouragement to dilettantism in medical science be deprecated, we think, if applied to the pre-eminent department of diagnosis, as must be the case when our author, as he declares in the preface, has confined himself "to the general rules of diagnosis, and taken but little notice of the exceptions that are met with in practice." Hardly a day passes in the busy practitioner's life during which he does not long for a more thorough and complete knowledge of diagnosis, even although he may have "memorized" the contents of Da Costa's and Barclay's admirable manuals; and yet his problems of disease are no more difficult to solve than those which meet the student at the very outset of his career as a medical man. We suppose a student's guide to geometry, in which the arduous *pons asinorum* and the abstruse forty-seventh theorem were omitted, might have a brief season of popularity among pupils of a low grade; but could it receive the sanction of any faithful and conscientious preceptor?

We have already remarked that the book is a good one; and by this we mean that it is well calculated to educate students into mediocre diagnosticians. Its arrangement is excellent, enabling us to turn at once to the portion of the work applicable to any particular case in hand, and to investigate the value and bearing of prominent symptoms without loss of time. Its usefulness is materially increased by the numerous (often superior) wood-cuts which are employed to illustrate the clear and concise descriptions of the text. The volume is well printed, and exhibits comparatively few evidences of careless writing or proof-reading; although we suspect that the statement on page 153, that oxalate of lime "crystals are octahedral (like envelopes)," might puzzle alike a student of medicine, a disciple of Euclid, and a stationer's apprentice. J. G. R.

AN INTRODUCTION TO PRACTICAL CHEMISTRY, INCLUDING ANALYSIS. By JOHN E. BOWMAN, F.C.S., late Professor of Chemistry in King's College, London. Edited by CHARLES L. BLOXAM, F.C.S., Professor of Chemistry in King's College, London, etc., etc. Sixth American, from the Sixth and Revised English Edition. Philadelphia, Henry C. Lea, 1873, pp. xvi., 339.

This work, which is a handbook for laboratory use, will be found of value to those who wish to make some headway in practical chemistry before taking up the more complete works on the subject. As its title implies, it does not enter into the consideration of theories, but confines itself entirely to practical matters, of which it is a concise and convenient exponent.

A SYSTEM OF MIDWIFERY, INCLUDING THE DISEASES OF PREGNANCY AND THE PUERPERAL STATE. By WILLIAM LEISHMAN, M.D. Henry C. Lea, Philadelphia.

This is a reprint of the English work noticed at length in our columns not long since. We have nothing to add to what was said at that time as to the professional merits and demerits of the book; and it only remains to state that the publisher has done his work in the present instance with his usual good taste and in his well-known style.

BLOODLESS SURGERY (*Irish Hospital Gazette*, November 1, 1873).—Mr. B. Wells Richardson has performed an amputation of the thigh by the bloodless method, compressing the limb with a tight bandage. The operation was that of Benjamin Bell, *i.e.*, by a long anterior flap. Only about one-third of the usual quantity of blood was lost.

GLEANINGS FROM OUR EXCHANGES.

NEURALGIA OF THE ABDOMINAL PLEXUS OF THE SYMPATHETIC.—Dr. A. Seeligmüller, in a collection of observations on the pathology of the nervous system (Halle, 1873), states that a man aged 33, who had been long exposed to cold and wet while employed in some water-works, and had afterwards worked in a white-lead manufactory, suffered from the following symptoms, which returned regularly every four weeks. His face became red, and he had pain in one or other of the lower limbs. While these symptoms were present, he had a violent paroxysm of cough, ending in vomiting of mucus; this was followed by an urgent desire for defecation, attended with spasmodic pain in the rectum and in the whole of the hypochondriac region. The first discharges were normal; afterwards they presented thready masses of the size of a goose-quill. After the stools, the pain extended to the back; and, when it had reached the neck, the feeling of strangulation, vomiting, and spasmodic deglutition, were relieved. The patient then had a rigor; and the paroxysm ceased at the end of twelve hours, with an attack of vomiting, to be repeated on the third day. After this, there was an interval of four weeks, during which the man became rapidly convalescent and presented nothing abnormal on examination. Various plans of treatment only alleviated this condition for a short time. The patient found most relief from a prolonged course of treatment as for tænia and faradization of the large intestine, and at a later date from injection of morphia. The disorder remained essentially unchanged. Dr. Seeligmüller believes that the symptoms were due to neuralgia of the solar plexus, or to a visceral neuralgia affecting some one or other of the abdominal plexus. He does not think that the case was one of lead-colic, because the patient had no symptoms while employed in the manufactory, and there was no lead-line on the gums.—*British Medical Journal*.

PARALYSIS OF THE THREE BRANCHES OF THE TRIFACIAL NERVE.—The same author (*ibid.*) refers to the case of a woman aged 26, in whom neuro-paralytic inflammation of the eye set in after nearly three years of anæsthesia of the left side of the face (this was at first limited to the left corner of the mouth, from which it afterwards spread upwards). The left half of the tongue was thickly coated with a white fur; the right was of a bright-red color; taste was lost in the anterior two-thirds of the left side of the tongue. A two months' course of treatment with the constant electric current (the positive pole being applied behind the left ear, and the negative to the face) produced marked improvement in all the symptoms.—*British Medical Journal*.

TYPICAL NEUROSIS OF THE VAGUS NERVE.—A girl aged 15, says Dr. Seeligmüller (*ibid.*), had suppression of the menses after being violently angry. At the same time, severe pharyngitis set in; and this recurred regularly for two and a half years whenever she had a paroxysm of anger. In the first half-year, she had loss of consciousness, tonic cramps in the hands and feet, and frequent dyspnœa, generally lasting four hours. The cramps and loss of consciousness afterwards disappeared; but she had recurrent paroxysms of enormously increased frequency of respiration,—200 in a minute. Numerous plans of treatment were employed without effect. Dr. Seeligmüller, having ascertained that pressure produced pain at points along the left side of the seventh, eighth, ninth, and tenth dorsal vertebrae, and in the corresponding intercostal spaces, used the constant current, applying the positive pole over the painful parts of the spinal column, while with the negative pole the points where pain was produced were

brought into contact until the pain had ceased. Each point was treated from two to four minutes, thirty or forty large Remak's elements being used. After two months of this treatment, the paroxysms almost disappeared. At a later date, the patient had other nervous disturbances, especially severe pains in various parts of the body. Dr. Seeligmüller believes the case to have been one of neurosis of the vagus nerve, the central end of which was abnormally irritated by inflammation proceeding from the throat. A search for painful points, and the application of treatment to them, is an essential indication in the treatment of all reflex neuroses.—*British Medical Journal*.

SCIATICA FOLLOWING THE CONTINUED USE OF A SEWING-MACHINE.—Dr. Seeligmüller relates (*ibid.*) the case of a woman, aged 50, who, after having worked with a sewing-machine for four years, had tearing pains in the leg with which she worked, extending from the ankle to the tuber ischii. The pain was not felt when she rested, but was brought on by walking or standing. The patient had also a sensation of cold and formication in the affected foot. Continued labor with the sewing-machine produced, besides the pain, loss of muscular power in the legs, wasting of the muscular substance, and a state of great general weakness. As a prophylactic measure, she was ordered to take longer intervals of rest between the periods of work.—*British Medical Journal*.

CASE OF POISONING BY COAL-GAS (*The Lancet*, October 25, 1873).—Dr. F. De Chaumont recently had the opportunity of making post-mortem examinations on the bodies of two persons who died from the effects of breathing an atmosphere saturated with coal-gas. He found extensive ecchymoses of a bright-red color on the dependent parts of the back, arms, and legs; the dura mater on its external surface was much congested; the arachnoid was opaque; the pia mater bright red and injected; cerebral substance bright red, with numerous bloody points in it; a small quantity of serum in the spinal canal; right auricle full of coagulated blood; blood generally fluid; trachea highly congested, containing a moderate quantity of mucus; lungs not much collapsed; aorta closed and crepitant; bronchial membrane greatly congested; bloody, frothy matter issuing in large quantities from the tubes. Remaining organs healthy.

SECONDARY DISEASE OF BOTH PNEUMOGASTRIC NERVES IN THE COURSE OF TYPHOID FEVER.—Dr. Zurlhelle relates (*Berliner Klinische Wochenschrift*, No. 29, 1873) the case of a man who, in the second week of an attack of fever, was seized with severe pain at the level of the cornu of the thyroid cartilage on the left side (and later also on the right), which seriously impeded deglutition. The voice was clear, and remained so. Nothing abnormal could be detected by examination with the laryngoscope or externally; but the pain was much increased by pressure in the direction of the spine. In the further progress of the disease, attacks of vertigo and palpitation set in, while the pulse became irregular and sank to 36 in the minute. Later on, there were frequent attacks of syncope, with clonic convulsions and profuse vomiting. The fainting-fits were diminished by morphia-injections; but, while the temperature was still high, the pulse remained irregular, less than 40 in the minute. Pneumonia of the left side now set in, and with it paresis of the recurrent nerve on both sides, as ascertained by the laryngoscope, and hoarseness. Under the use of iodide of potassium, the violent pain on both sides of the neck at once disappeared; the heart-beats became more regular and frequent, but hoarseness, due to paresis of the left recurrent nerve, remained.—*British Medical Journal*.

INTUSSUSCEPTION (*Irish Hospital Gazette*, November 15, 1873).—Dr. B. G. McDowell details the case of a woman, æt. 47, who on admission to the hospital stated that she had been ill four days, with incessant vomiting, and that during the last two days she had passed blood by the bowels in large quantities. She was very weak and exhausted, the pulse rapid and feeble, the extremities cold, and the surface covered with a dank sweat. During the next three days she grew weaker, her bowels remained closed, the vomiting became fecal, and she finally died.

On opening the abdomen, the large intestine was found to form a solid mass about six inches in length and four in diameter, situated horizontally in the middle line of the body below the stomach. This proved to be due to an intussusception, the ascending colon with part of the great omentum being included in the transverse colon. The contiguous serous surfaces were firmly adherent; the mucous membrane of both the including and included portions was intensely congested, almost gangrenous; the intestines were full of a large quantity of liquid feculent matter. The case is peculiar from the unusual situation of the obstruction.

YELLOW FEVER IN NEW ORLEANS IN 1873—ITS SPREAD ARRESTED BY DISINFECTANTS.—Dr. Alfred W. Perry, Sanitary Inspector of N. O. Board of Health, states (*New Orleans Med. and Surg. Journal*, November, 1873) that yellow fever was introduced into New Orleans, July 4, by the mate of a Spanish vessel from Havana, which arrived on the 26th June, and the disease then slowly spread. "During the first week in August the Board of Health commenced extensive disinfection with carbolic acid of all places where yellow fever had been reported. The disinfection was performed in two different ways,—viz., when a case of yellow fever was reported, all the yards, alleys, and drains in the square were sprinkled with carbolic acid by hand sprinkling-pots; about seventy gallons of the carbolic acid were used per square. This was done to destroy any disease-germs that might be on the ground, and to prevent the spread of the disease-germs over the other parts of the same square. Thirty entire squares and twenty-one half squares where yellow fever had occurred were thus disinfected in the Fourth District, and in only seven of these areas disinfected were there any subsequent cases of yellow fever."

The streets were also disinfected with carbolic acid by sprinkling water-carts. Nowhere in the world, Dr. P. says, has disinfection on so extensive a scale been used. "In sprinkling the streets, about twenty gallons were used to every one hundred yards; this was repeated several times at intervals of five to ten days. The large amount of carbolic acid used made the air of a disinfected locality exceedingly irritating to the eyes, and sometimes produced headache and nausea. These disagreeable effects are due to the naphtha and naphthaline, which constitute the impurities in the crude carbolic acid; these have no disinfecting value, and in future a purer acid should be used, which is not very unpleasant, and equally effective and cheap." He further says that a few cases occurred in Mobile, and the disease was extinguished by the same method.—*Medical News*.

COMPRESSION AS A MEANS OF PREVENTING HEMORRHAGE (*British Medical Journal*, November 1, 1873).—Mr. George W. Callender thinks there are some conditions in which the use of M. Esmarch's plan for the prevention of hemorrhage during operations by encircling the limb or part with an elastic bandage is not desirable. Cases where there is any suspicion of local vein disease are of this class; so, too, are cases in which primary amputation is required for the crushing of tissues, as in such the torn veins are closed with clots

which might possibly be displaced by the compressing bandage, and so pass into the larger vessels, causing embolism; and so also are cases of gangrene or of rapidly extending cellular inflammation. The expectation that the compression might prevent pain has been tested and has failed, but there is no reason to suppose that it engenders risk of the after-sloughing of parts, as of the skin-flaps after amputations. It may be serviceable in quite another direction,—as a compress in the immediate treatment of poisoned wounds. Dr. W. R. Kynsey reports (*Irish Hospital Gazette*, November 15, 1873) three cases in which this method was employed with great success: one of necrosis of tibia, one of amputation of a toe, and an excision of the elbow. There was no loss of blood, no necessity for the use of a sponge, and each structure before division could be easily recognized.

Dr. W. Thomson reports a case (*ibid.*) of amputation of the hand where the best possible results were obtained by the use of compression.

CAOUTCHOU ELECTUARY AS A REMEDIAL AGENT (*New York Medical Record*, November 15, 1873).—Dr. Theodore Varick, after having for fifteen years prescribed caoutchouc in preference to cod-liver oil in certain cases of pulmonary tuberculosis in every stage, in chronic bronchitis, the winter coughs of old people, and in chronic rheumatism, desires to call attention to its use as a remedial agent. It is not claimed that it is a remedy which has any specific action, but that it diminishes excessive mucous secretion and suppuration, arrests hemorrhage and colliquative sweating, and retards emaciation.

Prepared in the following manner, it should be given in doses of a teaspoonful three times a day, about two hours after meals:

R Caoutchouc (in thin slices), $\mathfrak{z}\text{i}$;
Olei terebinthinæ, $\mathfrak{f}\mathfrak{z}\text{ii}$.—M.

R Sol. caoutchouc, $\mathfrak{f}\mathfrak{z}\text{ii}$;
Sacch. alb., $\mathfrak{f}\mathfrak{z}\text{iss}$;
Mellis (strained), $\mathfrak{f}\mathfrak{z}\text{iiiss}$.—M.

When these preparations are mingled, the mixture (containing about two grains of caoutchouc to the teaspoonful) should be of an opaque yellow color and thick enough to run very slowly from a spoon. One hundred parts of caoutchouc contain 87.2 carbon and 12.8 hydrogen, while cod-liver oil contains of carbon 37 and hydrogen 34—; so that should the former be available as respiratory force or fuel it would be of great value.

LATENT SYPHILIS AS A CAUSE OF UNUNITED FRACTURE (*The Lancet*, November 1, 1873).—J. Wilson Steele, M.D., reports the case of a man, æt. 30, who was admitted to the hospital on March 17, suffering from an oblique fracture of the tibia at about the junction of its middle with its lower third. It was easily reduced, put up in two side-splints, and the redness and swelling subdued by evaporating lotions. He seemed to progress favorably, took his food heartily, and slept well. On removing the splints about the usual time, it was found that no attempt at union had taken place. There was no apparent constitutional cause to account for this, and the line of fracture did not run in such a way as to interfere with the nutritious artery of the bone. On April 24 the fragments were put firmly in apposition for the second time. The splints were again removed June 10, with the same result as before. Dieffenbach's method of exciting inflammation in the fragments was then resorted to without delay. On July 29 the pins were removed, having become loosened by suppuration. There was much tenderness at the lower end of the upper fragment, and a large quantity of pus was discharged through the

openings made by the pins. No examination of the limb was made for a few days, lest any callus which might have been thrown out should be disturbed.

August 10.—The limb presented the same sad state of affairs as before; patient restless; appetite much impaired.

August 12.—Considerable conjunctival injection of the left eye; patient feverish and delirious.

August 13.—Patient calm; face and body covered with an erythematous eruption; marked iritis in left eye. He was ordered one-twelfth of a grain of bi-chloride of mercury in combination with ten grains of iodide of potassium three times daily. The effect was very marked. The lymph became absorbed from the eye, the general health improved, and on September 8 he was discharged cured, still persistently denying that he had ever had any form of venereal disease, but admitting that he had been exposed to contagion exactly nine weeks before admission.

MISCELLANY.

A WESTERN DOCTOR OF THE OLDEN TIME.—The late Dr. Morehead was for many years a leading practitioner and medical teacher in Cincinnati. The *Nashville Journal of Medicine and Surgery* discourses of him editorially as follows:

"We first saw Dr. Morehead forty-three years ago, and heard his course of lectures then upon the practice of medicine. Very well do we remember the first Monday in November, 1830. We then entered the Medical College of Ohio as a student. All of the Professors that morning, at nine o'clock, were sitting round a long, wide table, and, commencing at one end, paying fee and taking ticket, the student continued until he made the entire round. To the best of my recollection, each Professor, that morning, got about six hundred dollars. I remember to have thought it quite a princely business, and looked upon those grave philosophers, as I took every one to be, with absolute awe, wondering if they had not descended from the gods, to have attained so wonderful a distinction! I stopped one of them on the street the next day, to beg of him a prescription to relieve a poor man, in my neighborhood, of a hemiplegia, and I had not a doubt but a few cabalistic hieroglyphics of his, on a scrap of paper, would confer on me the power of making my poor friend whole,—that he might leap, with recreated energy, and go on his way rejoicing.

"And now the lectures began. Except Cobb and the obstetrician, each of them sat down on a chair and read his lecture straight along from one end to the other, when, saying "Good-morning, gentlemen," he left, to make way for another.

"Morehead wore black buckskin boots, drawn on over his pantaloons, which were of black plush. I made no doubt that such boots were only for those in the highest walks of philosophy, and wondered if it were possible for any of his colleagues, or of the students before him, ever to attain so sublime a height as to be entitled to such boots as those. I had never seen any like them before, nor have I since. All the

other Professors trudged about on foot to their patients, if at any time they had any; but Morehead, who always had plenty of them, rode an old gray mare, heavy in foal. He was, I remember, quite a hero with the students, for he had "fit his fight" with Drake, and, it was said, got the best of it. The story ran that Morehead had a handkerchief—an old bandana, about the size of a tablecloth—full of silver dollars, which he was taking to the bank, when Drake met him on the street, and let loose upon his head a torrent of the bitterest and most eloquent invective, of the non-expletive kind, imaginable, for Drake never swore. Whereupon, being slow of speech, Morehead fell back on his muscle, and brought down on Drake's head his handkerchief of dollars, with such terrific force as to curl him up on the pavement, deprived of speech and sense, where Morehead left him, and went his way. Drake must have alluded to this conflict, five years later, when he said, in his farewell lecture to his class, in the 'Drake School,' out of taste, I thought, alluding to his 'sland'ers,' as he called his opponents, 'I have tried the pen, I have' (standing on his toes, and striking the desk with his fist) 'I have tried *physical force*.'

"Morehead had his lectures written on small note-paper, and carried the one selected for the day in a thick and rather greasy-looking pocket-book, which he would take from his side-pocket, after taking his seat, untie its fastenings, and, lifting sheet by sheet, read them as one might read a letter aloud at his own fireside. His brogue was terrible, and it was with the greatest difficulty that I could comprehend him. I believe a large majority of the class never tried. I never saw him make but one gesture. He was talking of salivation, and said, 'Some of your patients, hereafter, upon a morning visit, will' (and here he carried his forefinger and thumb to his upper right canine, and motioned as if extracting it) 'will reproachfully say, "See here, doctor."'"

"He had a large collection of pills, plasters, and things, in an old frame building fronting the levee, and a brother, as I understood, who was a 'surgeon,' and who was pretty generally on hand here, and, I remember, prescribed 'searching cathartics,' so popular with his brother. I did not hear that he did any other surgery.

"Dr. Morehead always said that he would prescribe for no one who did not have on a flannel shirt. He would not prescribe for a room-mate of mine until he got one, which was not an easy thing, in the absence of a subscription, for the poor fellow to do.

"Dr. Morehead got married, for the first time, during this winter, and on the night of the wedding the students had a meeting and appointed an 'orator' to congratulate him next day, at his lecture-hour. Sure enough, next day, just as the doctor was taking his seat, at a preconcerted signal the whole class arose, as one man, when our orator, a very tall, gaunt man, with enormous porter-house-steak whiskers, as red as blazes, fired away, and in hot haste was up among the stars, and walking the milky-way as fearlessly as a conjurer

dances on a tight-rope. When he was through, we all sat down, and so did the Doctor, and, leisurely taking out his old leather pocket-book, he untied the string, took out a sheet, and commenced reading, as if nothing in the world had happened!

"When he went to see a patient of whose financial rank he was ignorant, he no sooner entered the room than he asked, pencil and paper in hand, 'Who pays this bill?'

"Twenty years afterwards, we learned from a high source that Morehead, a native of Ireland, had never taken out papers of naturalization; that he possessed, in his own right, in Ireland, two hundred thousand dollars; and that he made and saved two hundred thousand more in Cincinnati, which he took with him to Ireland, where he lived a reasonable lifetime longer, on a magnificent estate."

THE *Lyon Medical* states that on opening, a short time ago, the will of a Mr. D——, the following clause was found: "I request that my body be delivered to the Paris Gas Company, for the purpose of being placed into a retort. I always used my mental powers for the enlightenment of the population at large, and I desire that my body be used to enlighten the people after my death." As cremation is not allowed by law in France, the request cannot be carried out.—*London Lancet*.

NOTES AND QUERIES.

WHAT would be the effect upon the human system of a hypodermic injection of chlorodyne? I ask the question owing to my having injected fifteen minims into a dog,—a *fair-sized cur*,—the effect of which was to completely narcotize him, and he remained so for at least two hours; so much so that if I had not noticed the pulsation of the heart I might have supposed him dead. After his recovery I tried half an ounce by the mouth, which seemed to have but little effect; I then tried one ounce per rectum, with the same result.

Yours truly,

INQUIRER.

Answer.

As the editor of the *Philadelphia Medical Times* has never heard of chlorodyne being used hypodermically, he cannot answer the inquiry. The results of the experiment are certainly quite startling, but are possibly explainable as the conjoint effect of the ext. cannabis and the morphia of the chlorodyne thrown directly into a vein. The resin of cannabis is absorbed very slowly and with difficulty, and hence its action when thrown into a vein would *a priori* be expected to be much greater than when it is taken into the stomach. After all, this is mere guessing: if any of our subscribers have any knowledge on the subject, we would be glad to hear from them, and we hope Inquirer will inquire into the matter by further experiments.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 9, 1873, TO DECEMBER 15, 1873, INCLUSIVE.

BAILY, JOSEPH C., SURGEON.—Relieved from duty in Department of California, to proceed to Baltimore, Md., and, on arrival, report by letter to the Surgeon-General. S. O. 244, A. G. O., December 8, 1873.

GHISELIN, JAMES T., SURGEON.—Granted leave of absence until June 6, 1874, and his resignation accepted, to take effect June 6, 1874. S. O. 245, A. G. O., December 10, 1873.

PATZKI, J. H., ASSISTANT-SURGEON.—Assigned to duty at Fort Fetterman, Wyoming Territory. S. O. 182, Department of the Platte, December 3, 1873.

PHILADELPHIA MEDICAL TIMES.

SATURDAY, DECEMBER 27, 1873.

ORIGINAL COMMUNICATIONS.

NATIVITY OF PARENTS AS AFFECTING THE FECUNDITY, AND THE PROPORTION OF SEXES IN BIRTHS IN GENERAL, AND IN THE TWIN, ILLEGITIMATE, AND STILL-BIRTHS IN PARTICULAR,

AS ILLUSTRATED IN THE VITAL STATISTICS OF THE STATE OF MICHIGAN FOR THE YEAR 1870.

BY JOHN STOCKTON-HOUGH, M.D.,
Philadelphia.

THE writer in the course of his statistical studies, in seeking facts to support theories, elaborated

from the "Fourth Annual Report (1870) of Births, Marriages, and Deaths occurring in the State of Michigan" (so excellently compiled by Dr. Henry B. Baker), a table exhibiting the effect of native, foreign, and mixed matrimonial alliances upon the proportion of sexes in the births from such unions; particularly the proportion among twin, illegitimate, and still-births.

In this table it will be seen that foreign parents have a larger proportion of male offspring, indicating that they are more prolific than native couples. And when the mother only is foreign, the proportion of males is still further increased; while native mothers with foreign fathers produce the smallest proportion of any.

The object of this paper is twofold: first, to point out these facts, and, in the second place, to explain the proximate cause of these differences.

*Births in the State of Michigan for the Year 1870.**

Total all Nativities¶	13,846	12,726	108.80	107.00	108.10	162.50	

In general, native mothers with foreign fathers produced 104.18 males to every 100 females, which is a smaller proportion of boys than where both parents are native (107.77 male to 100 female); while foreign mothers with native fathers produced 111.17 males to every 100 females, which is a *larger* proportion of males than where both parents are foreign,—viz., 109.31 males to 100 females. Where both parents are foreign, the proportion is 109.31 males to 100 females, while native parents produced only 107.77 males to 100 females, indicating, according to the law already enunciated by the writer, that under ordinary circumstances the greater the proportion of males in births the greater the fecundity.**

The fact of foreign fathers reducing the proportion of males (increasing the proportion of females) below the average, where both parents are foreign, and *even lower than where both parents are native*, is a significant one, which cannot help arresting our attention, and is worthy of careful consideration, pointing as it surely does to a *differential dynamic relationship*†† between the parental combinations.

As foreign parents produce a larger proportion of males than native parents, by our ordinary methods of reasoning we would naturally infer that a native

§*Ibid.*, p. 67.

¶*Ibid.*, pp. 63-4.

**While it cannot be denied that the number of births in any or indeed in all of these classes is insufficient to warrant us in fixing limits to the proportions in the various differentiations, we do claim that the deductions are in the main well founded, as the figures are called into play merely for the sake of illustrating, and thus corroborating, theories deduced from other sources.

††The Relative Viability of the Sexes; particularly with Regard to the Relative Liability of the Inheritance of Certain Transmissible Diseases, etc., etc. New York Medical Record, June 16 and July 15, 1873, pp. 9.

†† This theory of a differential dynamic relationship was first maintained in an inaugural dissertation (presented to the Trustees and Faculty of the Medical Department of the University of Pennsylvania for the degree of Doctor of Medicine, March 13, 1868), entitled "Prepotency, Sexual Elective Affinity, Non-Congeniality, or the Dynamic Differentiation of the Elements of Reproduction in the Human Species; the Cause of Relative Sterility," by John Stockton-Hough, M.A., M. Chem., of New Jersey; also in the article on Relative Viability, etc., above referred to, and in a paper on "Statistics relating to the Births, Marriages, and Deaths occurring in Philadelphia for the Eleven Years ending 1871,"—Penn Monthly, Philadelphia, September, 1873, pp. 599-620, and Proceedings of the Social Science Association of Philadelphia, September, 1873; also in a paper "On the Temperature of the Sexes—an Indication of Development,"—Philadelphia Medical Times, November 8, 1873, pp. 3; also in a forthcoming work on "The Proximate Cause of Evolution;" also in a paper on "The Cause of Rotation and Nearly Equal Number of Sexes in Births;" also in a paper "On a Certain Anomalous Condition of the Flowers of Zea Mays, as an Indication of the Relative Development of the Male and Female Plants,"—American Naturalist, January, 1874; also in a paper on "The Laws of Transmission of Resemblance from Parents to their Children,"—New York Medical Record, August 15, Part I.; September 15, Part II.; October 15, Part III.; November 15, Part IV., 1873, pp. 16.

coupled with a foreigner ought to produce a proportion of males between these two; but this is not the case, as we have shown, whether we couple the native man with the foreign woman, or the reverse. In the first instance the proportion of males is increased, while in the second instance it reduces it below the smaller proportion; in neither case, therefore, does it fall between the proportion where both are native or both foreign. This fact is a practical proof of the existence of the differential dynamic relationship between the elements of reproduction for which we contend in our theory.

From these figures it would appear that the foreign father has more power to diminish the proportion of males ($109.31 - 104.18 = 5.13$) than the foreign mother has to increase it ($111.17 - 109.31 = 1.86$) beyond that where both parents are foreign (109.31); while the native mother diminishes the proportion ($107.77 - 104.18 = 3.59$) more than the native father (foreign mother) increases it ($111.17 - 107.77 = 3.40$) beyond that where both are native (107.77).

TWIN BIRTHS.

By reference to the table we see that foreign mothers with native fathers had 171.42 males to 100 females in their twin births, while native mothers with foreign fathers had but 93.70 males to 100 females. Where both parents were native, the proportion was 96 males to 100 females, while both parents foreign gave 103.84 males to 100 females; thus following the same law with relation to the proportions in each combination as in the births in general.

In Rhode Island, in the nineteen years ending 1871, there were 853 plurality births, of which both parents were American in 44.5 per cent. (380) of the cases, foreign in 47.9 per cent. (409) of the cases, and mixed in 6.4 per cent. (56); while in the general parentage of all births (1858-1871) 45.34 per cent. were American, 44.76 per cent. foreign, and 9.90 per cent. mixed.

Here we also see that the proportion of plurality cases is greater among the foreign than among the American parents; and this fact, taken in connection with the above, confirms the rule already enunciated by the author,* viz.: the greater the fecundity, the greater the proportion of male births.

ILLEGITIMATE BIRTHS.

It will be seen in the table that native parents have a much larger proportion of males among the births of their illegitimate offspring than foreign parents, though the reverse is the case in the births in general. Foreign mothers have a much larger proportion of male illegitimate children than foreign fathers; thus further corroborating the rule of greater generative vigor of the foreign male.

I have already pointed out some of the causes of the smaller proportion of males among illegitimate

births, in my paper on the Statistics of Philadelphia. In it I have stated the causes to be as follows, viz.:

1. Greater proportion of first children.
2. Less advanced age of the mother.
3. Greater vigor of the father.
4. The presence of a condition incident to menstruation, causing the ovule to be fecundated at an earlier stage of development.
5. Want of stimulated ovarian excitement by previous procreative acts.
6. Immaturity of the woman, the system being exercised by vigorous growth, which is antagonistic to the development of the procreative faculties, principal among which is the maturation of ova.†

I believe it is a law that a high degree of fecundity is nearly always accompanied by a high rate of mortality; and we find this point illustrated in the State of Massachusetts. In the ten years from 1862 to 1871, of the children born of American families, 16.47 per cent. died under one year, and 26 per cent. under five years. Of those born in foreign families, 18.13 per cent. died under one year, and 32.79 per cent. under five years. The mortality of the foreigners' children was 10 per cent. greater under one, and 26 per cent. greater under five, than among the children of the natives.§§

STILL-BIRTHS.

Although foreign fathers with native mothers have the smallest proportion of males in their births

† Dr. Henry Hartshorne offers in explanation of this peculiarity the following: In illegitimate births, "where vital energy may be supposed to be above the average (sexual propensity overriding prudence and morals, and thus attesting its own strength), there are three per cent. more than the average number of females." "On the Relation between Vigor and Sex," Proceedings Am. Assoc. for Adv. of Sci., 1872, p. 196.

‡‡ Percentages of Population, calculated from Gen. Walker's Census Report of the United States, Washington, D. C., 1870.

§§ Dr. Jarvis, Mass. Report, 1873, p. 215, out of Mortality Reports.

* Longevity; or the Relative Viability of the Sexes, etc., etc.,—New York Medical Record, June 16 and July 15, 1873, pp. 297-302 and 353-405; also, in Statistics of Births, Marriages, and Deaths in the City of Philadelphia for the Eleven Years ending 1871,—Penn Monthly, September, 1873, pp. 599-620, and Proc. of Social Sci. Assoc. of Philadelphia, 1873.

in general, as well as in their illegitimate and twin births, yet when we come to examine the still-births we find the rule is reversed, and they have a far greater proportion of males than the foreign mother with the native father. And this *proportion* is increased when we take into consideration the fact of foreign fathers and native mothers having a much smaller proportion of males in the births in general, viz., 104.18 to 100 females.

The foreign father, therefore, would appear to disturb the harmonious relationship between the proportions of the child and the pelvic capacity of the mother more than the native father with the foreign mother. I am inclined to attribute this greater proportion of males in such cases to a disturbance of the harmonious* relationship above referred to, rather than to any appreciable deterioration or decline in the viability of the offspring under the circumstances, though the latter cause may be operative in a slight degree. If the latter cause be operative, it would appear to be a reflection on the native mother, as I have pointed out in another paper,† wherein it was shown that Massachusetts (18 years, 1852-69), with a proportion of only 105.8 males to 100 females in the births in general, had 146.6 males to 100 females still-born, while Philadelphia (11 years ending 1871), with 110.65 males to 100 females in births in general, had but 134.4 males to 100 females in the still-births. I may here repeat "my conviction in regard to the cause of a larger proportion of males (146.6) in still-births in the State of Massachusetts for the eighteen years mentioned, as being due to defective development, which I believe is clearly chargeable to the incapacity of the mothers. Wherever the proportion of males is high in still-births among parents of the *same nationality* who are treated by equally skilful accoucheurs, I am persuaded that it is a reflection on the mothers."

Of course, the proportion of males (200 to 100 females) occurring in the births where the proportion is 104.18 males to 100 females, indicates a much larger percentage of still-births in this class than in the other class, where there are but 150 males to 100 females still-born out of a proportion of 111.17 males to 100 females.

* Dr. Henry B. Baker, in the "Fourth Registration Report of Michigan, 1870," pp. 65-6, gives out an opinion which is corroborative of the view taken by the writer. His opinion is expressed in the following words: "Among physicians it is well known that there is a correlation between many portions of the body, the cause of which is not always apparent. There also appears to be, as a rule, a peculiar harmony between the size and shape of the head of the child and the size and form of the pelvis of the mother. A comparison of Table XV. with Table VII. suggests the question whether there may not be some disturbance of this harmonious relation when the father is of one nationality and the mother is of another."

† Dr. Playfair, in commenting on some of the conclusions arrived at in Mr. Fred. W. Lowndes's valuable paper on the Statistics of "Still-births" (Trans. Lond. Obstet. Soc., 1872, vol. xiv. pp. 283-303, p. 303), says that the results of Mr. Hayser's and Dr. Hamilton's experience and observation indicated "that the number of still-births diminished in exact ratio to the frequency with which the forceps were applied." Dr. Hamilton habitually used the forceps in about the ratio of one in every seven or eight labors, and obtained the unprecedented result of seven hundred and thirty-one consecutive labors without a still-birth. In view of these facts, then, the obstetrician, when engaged to attend a confinement, should inquire the nationality of the parents, and expect to apply the forceps from two to four times as frequently where the parents are of different nationalities, as where they are both natives.

‡ Statistics relating to Births, Marriages, Deaths, and Movement of Population in the City of Philadelphia for the Eleven Years ending 1871, —Penn Monthly, September, 1873, and Papers of Social Science Association of Philadelphia, pp. 24, p. 22.

Where both parents were natives, the proportion of males in still-births was smallest of all, viz., 127.27 males to 100 females; and where they are of the same American or foreign State, the proportion is slightly increased, viz., 135.71 males to 100 females. Where both parents were foreign (often of different nationalities), the proportion of males is increased more than two and a half times, viz., 320 males to 100 females, while parents of a different American or foreign state give a proportion more than three and a half times as great (450 males to 100 females) as where both parents are native. One would easily infer from all the above that the proportion of males in still-births among consanguineous marriages would be reduced to a minimum, at least so far as the harmonious correlation of the cephalic and pelvic parts was operative, however much the viability of the fœtus might be lowered.

Of 137 children who were still-born (in Providence, 1870),‡ 70, or one in 13.40, had American mothers, and 56, or one in 12.82, had Irish mothers.

The effect of a different nationality of either parent from the other on the proportion of sexes and percentage still-born is certainly very remarkable, and I trust statisticians will give more attention to the arrangement of the parent-nativity of children than they have hitherto done, in order that more extensive comparisons may be made in the advancement of biological science.

The United States census of 1870 gives only 99.89 males to every 100 females in the native-born population, while in the foreign-born population there were 117.01 males to every 100 females.

"Examining the records of New York City for 1870, we find that, while the number of *deaths* of natives is nearly double that of foreigners, the number of *births* of children, both of whose parents are *foreign*, is almost *four to one* of those whose parents are both native. For so great a difference there must be a cause. Dr. Nathan Allen§ ascribes it to a deviation from the normal harmony of development of all the organs and functions, owing to unsanitary modes of living amongst women, as well as men, in this country."||

In observing the relative fecundity of foreign and native parents, it must not be forgotten that the foreign element in the population, almost necessarily, in a newly-settled state, is principally of an age capable of reproduction, while among the natives there is a far larger proportion of children and the aged. Dr. Baker, the compiler of the Michigan report, calls especial attention to this point, and I cannot do better than quote his own words. He says, "It appears that the per cent. of all parents to total population was [in 1870] 4.24; the per cent. of native-born parents to native population, only 3.13; while the per cent. of foreign-born parents to foreign-born population was

‡ Dr. E. M. Snow's Report, 1870, p. 56.

§ Trans. Am. Med. Assoc., 1870, p. 381.

|| Henry Hartshorne, M.D., Proceedings of the American Association for the Advancement of Science, 1872, p. 197,—"On the Relation between Vigor and Sex."

8.19. It should be remembered in this connection that the foreign population includes, with slight exceptions, only those of an age capable of reproduction, while the American or native population is made to include all the children of both native and foreign-born parents, making the native population appear very large, and the per cent. of native parents to total native population very small."*

I have already enunciated the law, "the greater the fecundity (single births), the greater the proportion of males,"† and, as we have shown that foreign-born parents have a larger proportion of males in their births than native-born parents, they are consequently more prolific. In mixed parentage, the principle of sexual differentiation would tend to affect the application of this law to the relative proportion of sexes born to such couples.

The conclusions arrived at in this paper, from the theories supported, are as follows:

1. That foreign-born parents are more prolific and have a larger proportion of male children than native-born parents.

2. That where the mother is foreign-born and the father native the fecundity is greater, and the proportion of males in the births, in general, is also greater, and among the still-births less, than where the mother is native and the father foreign-born. It is the mother, then, who principally controls the fecundity.

3. That the begetting of males on the part of the mother requires a more perfect or thorough (developmentally higher) procreative faculty than the begetting of females.

That the begetting of females on the part of the father requires more procreative vigor on his part than the begetting of males.

4. If it be true, as was alleged by Sir James Y. Simpson‡ and others, that the increased proportion of males in still-births is principally due to the greater size of the male foetal head, then the greatly increased proportion of males (from 135.71 to 450) in still-births among children whose parents are of different nationalities, over those of the same nationality, points to a larger brain as the result, and argues much in favor of cross-breeding as a means of improving the stock.

From an examination of the table it would appear that the foreign *father* from his alliance with the native mother is principally responsible for the great excess of males in still-births from such a union, as compared with the number of still-born to foreign-born mothers with native fathers. This view of the matter would seem to indicate that foreign-born fathers propagate greater cephalic foetal development than native fathers, or that the pelvic capacity of native mothers was less than that of foreign-born mothers; probably the latter is principally operative.

2003 WALNUT STREET, PHILADELPHIA, September, 1873.

A CASE OF FALLOPIAN PREGNANCY, WITH RUPTURE OF CYST, AND DEATH IN THIRD WEEK.

BY J. H. CATHCART, M.D.,
Philadelphia.

THE following case may be of interest to the profession, not only on account of its rarity, but also from the extreme difficulty of making a correct diagnosis, and the little benefit to be derived from any treatment.

A few weeks ago, November 8, 1873, about eight o'clock P.M., I was called to see Mrs. H., a fine healthy-looking mulatto woman, about 26 years of age. I found her suffering from a rather severe pain in the left iliac region, which had been present more or less throughout the day,—not bad enough, however, to prevent her from performing her usual household work. This pain had increased in intensity towards evening so as to compel her to send for me.

I found her in bed, lying on her left side, and complaining of the excessive pain in that part. Her pulse was feeble and 98 in the minute, respiration 48 and entirely thoracic. The skin was cool and moist. The bowels had been opened only a few minutes before I saw her. She complained of extreme nausea, but had vomited only once. The mind was clear, and she could converse quite rationally.

I prescribed a slight anodyne, with ammonia and brandy every fifteen minutes, but before the time for the third dose of the anodyne the pain had entirely left her, so it was omitted. I saw her again at nine o'clock, and found her absolutely pulseless, with the body and extremities cold. The heart was beating very irregularly, so that it was useless to count it. The carotids were the only arteries in which I could detect any pulsation whatever. The head was cool and covered by a cold, dewy perspiration. She was somewhat stupid, it being necessary to repeat a question in loud tone to arouse her or receive a reply, though it was always correctly and rationally given. She presented, in fact, the whole *ensemble* of collapse.

I endeavored by all possible means, by stimulating her, by warm applications to the extremities, and otherwise, to rally her, but in vain; though towards eleven o'clock there was a slight increase in the temperature of the skin, and the pulse might be felt at the wrist, but very feebly. Her mind was not so clouded, and she appeared better generally, and inclined to sleep. But, in spite of all we could do, she began to sink, and a few minutes before one o'clock she expired, passing away without the slightest struggle or indication of pain.

I was quite at a loss for a cause for such a sudden end. She had presented no toxic symptoms, neither was there any history of aneurism or heart-trouble. Nor was there anything to draw my attention particularly to the sexual organs: in fact, there was nothing in her previous history or in her present condition fully to account for her trouble.

She had been extremely irregular in her menstrual periods ever since her marriage, which had

* Fourth Registration Report, 1870, p. 41.

† Article on Relative Viability of the Sexes, etc., Med. Rec., June and July, 1873; also, Statistics of Philadelphia, Papers of Philadelphia Social Sci. Assoc., from Penn Monthly, September, 1873, p. 22.

‡ "Sex of Child as a Cause of Difficulty,"—Edin. Medical and Surgical Journal, October, 1844, p. 387, and Gynaecological Works, N.Y., 1871, pp. 307-63.

taken place four years ago. She had had her last sickness but three weeks before the time I saw her. This she told me herself, and was corroborated by her husband, who also informed me that there had been a very slight show the Monday previous. She had complained for several weeks of extreme tenderness on pressure and a constant pain in the region of the left ovary. She had had one child three years ago, and in January last had miscarried when in the third month of gestation.

On a post-mortem examination, which was made thirty-four hours after death, by Drs. Porter and Willard and myself, all the abdominal organs presented a healthy appearance. The cavity of the peritoneum was filled with blood,—more fluid than coagulated,—in quantity more than a gallon and a half. The uterus was retroflexed, the fundus lying fairly in the hollow of the sacrum.

The uterus and upper part of the vagina were removed, and presented a completely bloodless condition. The right Fallopian tube was crooked and contorted; the fringes of the fimbriated extremity are partly adherent, but the orifice is not entirely occluded; the probe of an ordinary pocket-case can be passed up three inches. There are bands of old transparent adhesions between the ovary and extremity of the Fallopian tube, and broad thin bands attaching the right ovary to the posterior surface of the uterus.

The extremity of the left Fallopian tube is in the same condition as that of the right. There are some evidences of previous inflammation between the posterior surface of the left Fallopian tube and the ovary, and there are broad bands connecting the posterior surface of the left ovary and its right extremity with the posterior surface of the uterus. A probe can be passed up the left tube about three and one-eighth inches; at this point there is a partially collapsed cyst, which is vascular with small vessels ramifying on its surface. This cyst is about one and three-eighths inches long by seven-eighths of an inch broad, and is oval in outline. On its upper surface, a little posteriorly and a little nearer its inner than its outer end, is a round orifice, from which projects a yellowish-reddish fringed mass which resembles a clot of blood. It was from this opening that the hemorrhage occurred.

Upon opening this cyst it is found to contain anteriorly two dark-colored soft coagula the size of peas, and a reddish-yellow mass which is rough and shaggy on its exterior. Upon opening the latter it is found to contain a second cavity the size of an almond-kernel; this is lined by an exceedingly delicate, thin membrane, resembling in appearance a serous membrane. No fluid was discovered in it. This cavity, so far as we are able to discover, does not communicate with the orifice from which the blood escaped.

This yellowish mass is undoubtedly a product of conception: when a small portion of it is placed under the microscope, it is found to consist of placental tissue, and the branched villi of the chorion, curved with an epithelial layer, are everywhere visible. At first it was thought that the cells which compose the tissue proper of the villi were in a

state of commencing fatty degeneration; but on a more careful examination this was found not to be the case.

Between the cyst already described and the left side of the fundus of the uterus is a second tumor, which is nearly round in outline, regular in shape, one inch long by three-fourths wide; it is not vascular on its exterior; it is dark-colored, and feels as if filled with a semi-solid substance. Upon opening it it is found to be filled with a soft coagulum of blood, the exterior of which is dark-colored, and the interior is of a Spanish-brown color and has a granular appearance. The fluid portions of the blood have largely been absorbed. There are trabeculae running across, and the lining membrane is smooth. There is no communication between the two cysts, and neither can be entered from the uterine orifice of the Fallopian tube.

Both ovaries are large and healthy, and at the inner extremity of the left one is a large corpus luteum one-half inch in diameter, and the orifice through which the ovum has escaped is plainly visible and only recently closed. There is no corpus luteum in the ovary of the right side.

The uterus is four inches long, and its walls are about seven-eighths of an inch in thickness; the cavity is three and one-eighth inches long, and the cervix is filled by a thick amber-colored plug of mucus. The lining membrane is pale, thick, and spongy, and appears to be covered by a thin, delicate exudation. The microscope shows the mucous membrane hypertrophied, the glands enlarged, and the inter-glandular tissue in a state of proliferation. The muscular constituents of the organ are also enlarged and easily studied in all their detail of structure. The whole organ appears, in fact, to be undergoing a physiological change in sympathy with the process taking place in the Fallopian tube, and resembling closely that which takes place in a perfectly normal pregnancy.

The most important feature of this case is in the early rupture of the cyst: the foetus is undoubtedly under twenty days' development in appearance, and the history of the case would appear to corroborate this age.

Out of a record of two hundred and twenty cases of extra-uterine pregnancy, there are sixty-one occurring in the Fallopian tube, and of those which terminated within the second month there are only four cases reported,—viz., by Langstöff, in *Transactions of the Medico-Chirurgical Society of London*, 1817, vol. viii. p. 502; by Littré, in *Mém. de l'Acad. des Sciences*, for 1702, p. 209; by C. D. Meigs, in the *Medical Examiner* of November 9, 1839, p. 709; and the case of Ollivier (d'Angiers), *Archives Générales de Médecine*, second series, p. 403, mentioned by Bernutz and Goupil in *Clin. Memoirs of Diseases of Women*, New Syd. Soc., 1866, vol. i. p. 236. There is a fifth case reported by Dr. R. P. Harris, of this city, in the *Proceedings of the Pathological Society of Philadelphia*, vol. i. p. 302, in which the cyst ruptured at the fourth week, or about the time there was an attempt at menstruation.

These are the only cases I have been able to obtain any record of in which the rupture took place

so early: so that in the present case the rupture of the cyst is without parallel as to its time of occurrence.

[We would call attention to the exceedingly interesting discussion this paper gave origin to at the Pathological Society, as reported in the current number of the *Philadelphia Medical Times*.—ED.]

ESMARCH'S METHOD FOR BLOODLESS OPERATIONS.

BY W. W. KEEN, M.D.

THE practice of diminishing the amount of blood lost in an operation by elevation of a limb, and by bandaging it before the application of a tourniquet, is nothing novel in surgery. The method lately introduced into practice by Prof. Esmarch, however (see *Philadelphia Medical Times*, November 22, 1873, p. 125), produces an utterly new result, viz., an *absolutely bloodless operation*, as if on a cadaver. The advantages are manifest. Fewer assistants are needed; the parts are not obscured by blood, nor the operator annoyed by the necessity for sponging; the most careful dissections can then be made precisely as if on the dead subject; a prolonged operation involves no more loss of blood than a trifling one; and, more than all, the patient is saved the shock and depression caused by the hemorrhage,—in fact, he has gained, as if by transfusion, the blood that was in the amputated part.

The method being new, I have thought it best to report the following case at once, as the interest lies in the method of operation, and not in the result of the case, though that is, so far, a favorable one.

Edward Lee, æt. 20, of a scrofulous constitution, had caries of the left tibia, at the age of eight, with slight caries in the right tibia, and also in one of his ribs, but recovered completely. Nearly a year ago, following a blow, he had a return of the disease in the left tibia and the tarsus. When I first saw him, last July, he was so exhausted that I scarcely believed it probable he would live two weeks; but under careful attention, good diet, tonics, etc., he improved, till his condition has been quite favorable for the healing of the caries for some months past. After waiting till he began to fail rather than improve, I operated on his leg, December 9, 1873, with the assistance of Drs. Allis, Allison, and Bray, and several students. Dr. Allis administered the chloroform by his new apparatus, which used but three and a half drachms in the thirty-five minutes, or six minims a minute.

I obtained from Mr. Levick, on Chestnut Street below Eighth,* a bandage of pure rubber two and a half inches wide and five yards long, made of four strips hastily but strongly joined together. Beginning at the toes, I applied the bandage up to the middle of the thigh, keeping it on the stretch all the while, and making no reverses, as the elasticity of the bandage removed the necessity. At its upper border I wound tightly around the thigh a rubber tube five

feet long and half an inch in diameter, with a quarter-inch calibre, encircling the thigh four times, and securing the ends by the simple hooks used for dissection. It will be observed that this is a very difficult place to compress the femoral artery, as it lies deep among the muscles. I now removed the elastic bandage, and the leg was as blanched as that of a cadaver. For fear the method might not succeed, I applied a tourniquet loosely around the thigh, above the rubber tube, but found it a needless precaution.

I then cut down upon the bones and examined them with a view to resection, but found the disease far too extensive to admit of it: so I at once amputated by the flap method, just below the tubercle of the tibia. Not a *single drop* of blood was lost up to this time. I used the sponge only once while examining the bone, in order to remove the serum which exuded from the oedematous soft parts. The condition both of the soft parts and the bone was most readily determined by the eye, as they were unobscured by any blood, and the flaps were so pale that they resembled veal in color. Having secured the anterior and posterior tibial arteries and a large muscular branch, I gradually loosened the rubber tubing, when the blood returned to the stump, and some small arteries bled, but not till the last turn of the tubing was loosened, so perfect was the compression. Two additional ligatures on muscular branches were required, and three more were twisted, a little cold water stopping the rest. The total amount of blood lost during this last stage of securing the smaller arteries which could only be discovered by their spirting was less than one ounce.

December 13.—The stump was dressed with pure laudanum for two days, and after that with nothing. So far, not an unfavorable symptom has occurred. No pain or other trouble has resulted from the compression by the tubing. Scarcely any shock followed the operation, and since the first few hours the patient expresses himself as feeling far better than before the operation. He sat up in bed yesterday, three days after the operation.

P. S. December 19.—Delay in printing the case enables me to report that he was out of bed on the seventh day, and all of the wound has now united, except about one and a half inches.

In reply to the criticism of "Unguis" on Esmarch's method, in the issue of this journal for December 13, I beg leave to call his attention to the first two sentences in this communication, which was written before his article was published. The practice of previous surgeons resembles that of Esmarch, but is really totally different in its results. It is the old story of Dromio of Ephesus and Dromio of Syracuse. I venture to doubt whether "Unguis" or any other surgeon ever saw a bloodless amputation or resection before Esmarch taught us how to make it.

* At my suggestion, Mr. L. has made continuous bandages one and a half and two and a half inches wide, of any length.

M. GUÉNIOT reports (*L'Union Médicale*, November, 1873) a case of fatal operation for strangulated hernia in a child three months old.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, DECEMBER 27, 1873.

EDITORIAL.

TO OUR CONTRIBUTORS.

THE experience of the last few weeks has been of such character, the time consumed in personal interviews and in letter-writing has been of such amount, as to convince us of the propriety of saying a few words from the editorial chair to the contributors to the journal. In the first place, we desire to thank the numerous contributors for the zeal they have displayed in sustaining the Original Department of the journal,—a zeal whose fruits are shown in the fact that the appropriate drawer in the editorial sanctum contains enough original matter to occupy the columns of the *Times* to the middle of February,—a zeal, too, not without knowledge, as the quality of this matter will, we think, testify, when we lay these numerous papers before our readers. An embarrassment which grows out of this most desirable repletion is that some communications must wait publication for a greater or less length of time. We certainly think it only right for the interest of the journal and for the good of the contributors that editorial judgment should be exercised in holding some papers back and pushing others forward. It is evident some memoirs will keep, and some will not keep,—that a paper on the latest novelty will lose its freshness if not put forth at once, while a communication copied from some ancient papyrus, although perhaps no less interesting, and it may be even more important, than the other, can tarry a short time in the editorial sanctum without suffering.

So far as may be consistent with the best interests of all concerned, communications shall, however, appear in regular order; but we earnestly hope that no one will judge our valuation of his communication by the early or late appearance of it.

Again, no young or old author need worry himself about the non-acceptance of his paper, for, at least until further notice, all papers not accepted shall be returned at once.

If our contributors will pardon our boldness, we would ask them to remember the fact that, in this era of high pressure, high-pressure condensation is most desirable; that when an idea is stated clearly in ten lines it is read by ten times as many people, and remembered ten times as well, as if it had been put in a hundred lines.

When a contributor in the city desires to correct the *proofs* of his article, he should always write upon the MS., near the heading of it, "Send proofs to Dr. —, address, so and so." Otherwise, proofs will probably not be received.

The only conclusion we can draw from the very great influx of good original papers is that our contributors share the opinion which we hold, and have expressed before,—that it is possible to build up here in Philadelphia a medical paper which, as an exponent of scientific clinical medicine, shall take rank with any other in the world; which shall be a centre to give consistency and force to medical public opinion, both in its action upon the individual members of the profession, and, what is even more important, in its influence upon the world outside of the profession. Every little while we see evidences that the *Times* is wielding such an influence,—an influence which, although perhaps weak at present, we trust may grow, and be ever used for the perfecting and the exalting of our profession. We are informed that the City Board of Trusts have quietly abandoned their position in regard to the Sunday clinics, and we think our readers will agree with us that Dr. Sly will be for some time more sly and less open in his advertisements than he has been. In order to increase this influence, it is necessary that the circulation of the journal be increased. It is directly to the interest of every contributor that the circle of physicians whom his contribution reaches shall be widened. It is also directly to the interest of every one of our present subscribers that our circulation be increased. The reason our paper is not so large as a London weekly is simply that the subscription-list does not warrant the outlay. The *Philadelphia Medical Times* is to-day one of the cheapest journals in the country,—if indeed it be not the cheapest,—costing the subscriber only an infinitesimal

tesimal fraction over half a cent for a double-column quarto page. In the last six months we believe it has been more extensively quoted than any other American journal, both at home and abroad. We think, then, our contributors and subscribers can conscientiously recommend the journal to their neighbors. We feel that it is the interest of the whole profession of the country to have what it has never had in this country, a popular weekly medical journal comparable to the London papers, representing no interest but that of the general profession. The publishers of the *Philadelphia Medical Times* do not run it with the idea of making money out of it directly,—are willing to spend all they may receive. Will you not, then, induce your friends and neighbors to subscribe for the *Philadelphia Medical Times*, and aid us in reducing the price of the journal to one-quarter cent a page?

LEADING ARTICLES.

PROFESSOR AGASSIZ.

BY the death of Professor Louis Agassiz, which occurred in Cambridge, Mass., on the evening of December 14, this country has suffered a loss of the greatest magnitude, and one which is perhaps altogether irreparable. There remain men equally eminent in some departments of science, men of equal ability as public expounders of scientific truths, and men whose earnest and self-sacrificing devotion to scientific labors cannot for one moment be questioned; but there is probably not one who, combining in himself all these elements of success, possesses, in addition, the skill in observation, the personal magnetism, the noble singleness of soul, the great originating and organizing talent, and the ceaseless untiring energy which characterized Professor Agassiz, and enabled him to become the father of popular scientific education in America, and one of the greatest natural philosophers the world has ever produced.

It is a rare combination of qualities which enables an individual to conduct work requiring exhaustive industry and minute research; to make the broadest generalizations from the results of his own labors and those of others, and at the same time to so impress the public mind with the value of those labors as to draw forth thousands of dollars as contributions to the cause of science. It was through his influence that the government of Massachusetts was induced to appropriate money for the erection and support of a museum of natural history; it was by his advice that the United States Coast Survey

organized expeditions and explorations which have proved to be of the highest practical importance; and it was his zeal and enthusiasm which incited private citizens to assist in defraying the large expenses of those expeditions, and to furnish money and land for other purposes equally dear to him.

Much of his success in these particulars was undoubtedly due to his quick, sympathetic temperament, his native tact and eloquence when discussing any subject on which he felt deeply, and his remarkable self-denial in the pursuit of that science to which his life had been so thoroughly and completely devoted. There are few instances, apart from those of religious fanaticism, of such utter abandonment of ordinary aims and ambitions, and of such intense concentration of all mental and physical energies upon one idea; but with Prof. Agassiz the breadth, scope, and comprehensiveness of that idea raised him far above the level of all fanatics, whether religious or scientific. Although his opportunities for turning his knowledge and reputation to pecuniary profit were many, he invariably and consistently refused to embrace them, partly because he felt that he had "no time to make money," and partly because he was unwilling to overstep by a hair's breadth the strict limits within which he knew himself to be unquestionable authority. It was chiefly for the latter reason that he refused on one occasion to visit a tract of land situated but a day's journey from Boston and owned by a company engaged in an honorable and reliable undertaking. He would have been asked merely to certify to well-known and authenticated facts, and thus add the weight of his name to the venture; but he declined, though conscious that in doing so he lost a ten-thousand-dollar fee, because, as he expressed himself in conversation, he felt that there were others whose labors and studies had better fitted them to give an opinion entitled to respect. While thus prompt to refuse to go beyond his self-appointed sphere of thought and action, he was equally prompt to resent interference from those whose knowledge and researches he knew to be superficial and limited; and any suspicion of imposition or falsehood was sufficient to excite in him the most profound contempt. Thoroughly honest in all his convictions, making no effort to appear what he was not, and never influenced by any but the most upright and conscientious motives, he despised all hypocrisy in others, and above all in those who prostituted science to what he considered mere personal aggrandizement.

He was not, however, quixotic in his ideas, nor did he imagine that all men should conform to one

standard, or be devotees to abstract truth; but, on the contrary, he held in great respect all honorable success, either commercial or professional.

Having once deliberately chosen his position in an argument or controversy, he was slow even to obstinacy in yielding an inch to an opponent; and his bitter opposition to Darwinism is scarcely less memorable than his pertinacious defence of his celebrated glacial theory, and of his claim to priority in its origination. Although he let slip few opportunities of expressing his uncompromising hostility to the doctrine of evolution, he never made the mistake of confounding the theory with the theorist, and he invariably spoke in the highest terms of Mr. Darwin. On one occasion, while delivering a chatty afternoon lecture on shipboard, after having spent some days in cruising among the Galapagos Islands, one of the scenes of Darwin's early labors, he alluded to the impossibility of visiting that region, or, indeed, of approaching any scientific subject at the present day, without thinking of that gentleman, and sincerely and heartily eulogized him as "a keen observer, an indefatigable laborer, an honest, conscientious, and pains-taking investigator, and one of the most lovable of men."

He valued highly the opinions of those whom he knew to be his peers in the scientific world, but, as a rule, entirely disregarded all criticism of himself or his doings, whether favorable or the reverse.

His personal appearance was of the most prepossessing character, and his manner cordial, good-humored, and markedly free from constraint. He was somewhat under the medium height, with a massive head, bent slightly forward, and resting on a thick-set sturdy frame. His keen bluish-gray eyes always had a laugh lurking in their depths, and never failed to show a kindly and affectionate interest in those who approached him for help or sympathy. His hands were sinewy and firm, and so educated to precision and accuracy of movement by many delicate dissections that at the age of sixty-five he shaved his face daily without the aid of a glass, never omitting to do so even while at sea during decidedly rough weather. His manner took no note of social rank or station, and he was equally affable to an admiral or a common seaman, to a prince of the blood or a fish-huckster.

He was always ready and pleased to impart information to any one seeking it in the proper spirit, and did so in the clearest and most charming manner imaginable, making the dullest subject seem interesting, and investing it with a more extended significance by some illustrative or cognate fact.

His command of language was remarkable: he

could deliver an extemporaneous address in either French, German, or English, rarely hesitating for a word; and though when he used the latter tongue a slight foreign enunciation was observable, it could hardly be called an accent.

There is space for but a brief account of his life, the general outline of which is familiar to nearly all educated Americans. Louis John Rudolph Agassiz was born at Motiers, Canton of Neuchâtel, Switzerland, May 28, 1807. He was of Huguenot descent, and his lineal ancestors for six generations were clergymen, his father being pastor of the Protestant parish of St. Imier. His mother, who was the daughter of a physician, commenced his education, which was at first intended to fit him for the ministry, but was subsequently, owing to his strong natural inclination, directed towards the study of medicine. Indeed, in later life, although he never spoke disrespectfully of the clergy as a class, he said with much feeling that they were the most determined and obstinate adversaries with whom he had had to cope in his struggle for popular scientific education, and it seemed evident to at least one of his hearers that he compared the professors of theology rather unfavorably with those who cultivated the more exact sciences. His studies were continued at the Gymnasium at Biel and the college at Lausanne, after leaving which he went to the medical school at Zurich, and thence to the University of Heidelberg, where he studied anatomy and physiology under Tiedemann, zoology under Leuckart, and botany under Bischoff. He seemed always to retain his affection for this university, where, although it was not his *alma mater*, he won great distinction as a student, and recently he recommended it as the most pleasant of the European colleges for scientific labor.

At the age of twenty he entered the University of Munich, studied under Oken and Martius, made investigations in the embryology of animals with Döllinger, at whose house he lived, and began the publication of brief treatises on special subjects. On the return of an exploring expedition from Brazil he was appointed to compile for publication the discoveries relating to fishes, and after engaging in this work he abandoned the Æsculapian art, having graduated as Doctor of Medicine at Munich and obtained the degree of Doctor of Philosophy at Erlangen.

During his studies in Paris in the investigation of fossil fishes he became acquainted with Cuvier, whose influence upon him is said to be discernible in many of the views with which Agassiz was afterwards identified. It was doubtless about this time also that he

acquired the familiarity with the contents of the European museums of ichthyology, which enabled him all his life after to say with almost absolute certainty how many duplicates of any particular specimen were in existence, and what was their precise condition and state of preservation. He was almost the sole author of the science of fossil ichthyology, his great work upon which he was enabled to publish through the liberality of Baron von Humboldt. This was followed by his work on the fresh-water fishes, by the *Nomenclator Zoologicus*,—an index of names and classification for the entire animal kingdom,—and the *Bibliotheca Zoologiae et Geologiae*, containing a list of authors on natural history subjects, with critical notices of their writings. Professor Agassiz himself attributed his success partly to his intimate knowledge of the manner of working of his predecessors and the results obtained by them, and frequently remarked that students generally, and particularly medical men, were too apt to consider as useless whatever was a little antiquated or out of date.

In 1837 he propounded his glacial theory, one of the most original conceptions in the whole arcana of science; and ten years later he published his *Système Glacière*.

In 1846 he came to this country, and the following year accepted the chair of zoology and geology at Harvard; and thenceforth he spoke of himself, and was proud to be considered, as an American.

Although he was the constant recipient of testimonials and offers from abroad, he absolutely refused all, preferring to remain among the friends with whom he had become identified, and in a country he so greatly honored by his labors. In 1848 he went to Lake Superior, and in 1850 to the Florida Reefs, both journeys being productive of most valuable results. In 1865 a Boston merchant defrayed the expenses of his celebrated expedition to the Amazon River, during which thousands of new species were discovered, and the museum at Cambridge was enriched by many valuable additions.

In 1871 Professor Agassiz left Boston, in the *Hassler*, a vessel equipped by the United States Coast Survey for the purpose of taking deep-sea soundings, and furnished through private liberality with the means of securing and preserving zoological specimens. This was probably his most important expedition, as it was certainly, in his own opinion, the most interesting. His success in collecting was wonderful, and probably about one hundred and fifty thousand distinct zoological specimens were sent home during the cruise, three thousand five hundred gallons of alcohol being used in their

preservation. The figures are interesting, as illustrative of the scale on which he always worked when not hampered by want of means. He had hoped to announce the importance of this collection within a twelvemonth, and had already devoted considerable attention to the family of Selachians, studying with great care their modes of dentition and characteristics of growth and reproduction. His generosity with money was almost princely, and no price was too high to pay for a coveted specimen; yet all his life long it displeased him to see any one waste a scrap of writing-paper, and his manuscript was always finely and closely written, with no blank lines or spaces. He was unable to forget the times when his income was five hundred dollars a year, half of which went to artists for drawings, one hundred and fifty more being expended for books, and the remainder devoted to his personal expenses. In those days he was compelled to economize even his writing-paper, and thus formed a habit which he never outgrew. During the Hassler expedition it was very observable that in all countries the mere name of Professor Agassiz was sufficient to insure marked attention from every one, and individuals of all ranks and classes proved themselves not only willing but eager to give him every possible assistance. His sixty-fifth birthday was celebrated in the heart of the Andes, a mile above the level of the sea; and on that day he seemed so well and so full of health and vigor, that the wishes of "long life and continued success," though destined to be unfulfilled, seemed far from unreasonable. He considered that the result of the Hassler voyage was to place the Cambridge museum "actually in advance of all existing institutions in zoological researches."

On his return, with but a very brief interval, he commenced the foundation of a natural history school at Penikese Island, which was presented to him for that purpose, together with a large sum of money, by a New York gentleman. The primary object of this undertaking was to encourage teachers to dispense with books and employ natural objects in giving instruction, and its success seemed almost assured.

He had suffered for some time with brain-trouble,—according to his own views, a chronic inflammation of the *crura cerebri*,—which was invariably aggravated by excitement or over-exertion, either mental or physical. His weighty responsibilities and diversified enterprises, added to the intense and eager interest which he always took in any pursuit in which he was engaged, perhaps hastened the fatal conclusion of his labors. At his death he was a member of the French Academy of Sciences, of the

Royal Society of London, and of our own National Academy of Sciences. He held the Monthyon prize and the Cuvier prize from the Paris Academy, the Wollaston medal from the Geological Society of London, and the medal of merit from the King of Prussia. The Edinburgh and Dublin Universities had conferred their degrees upon him.

In special departments of natural science he has probably been excelled by not a few; but taking the whole round, including zoology, geology, palæontology, and their allied subjects,—embryology, comparative anatomy, etc.,—he had attained a uniform degree of eminence which has been rarely, if ever, equalled. As a public lecturer he seldom failed to kindle in others the enthusiasm which glowed within himself, and his success gave an impetus to science in this country which it had never before received. Certainly no one ever brought to any occupation a more profound sense of its grandeur and nobility, a loftier estimate of its relations to mankind, or a more steadfast purpose to consecrate his whole life to it, than did Professor Agassiz to the study of nature; and his feeling of reverent humility is frequently noticeable in his writings. "Even though we can make ourselves conscious that the works of nature are built by mind, and that it has pleased the Maker of all things to give us a spark of that life which makes us to be His children, formed in His image, that evidence is nowhere stronger than in the fact that our mind is capable of studying those works to a limit which approaches to a comprehension of their wonderful relation to one another."

In his daily intercourse with his family and friends Professor Agassiz was simply faultless; and in tone, manners, and deportment he was everything that befits the perfect gentleman. No one who knew him could fail to love, respect, and venerate him, and to feel his death as a personal loss and affliction; but he has been mourned over the whole land with a sincerity which shows how high a place he had won in the hearts of the people of his adopted country.

"His life was gentle, and the elements
So mixed in him that Nature might stand up
And say to all the world, *This was a man.*"

J. WM. WHITE, M.D.

ICE IN THE TREATMENT OF FACIAL NEURALGIA.—M. Wenteritz reports a case of very intense facial neuralgia, which resisted every mode of treatment, that finally yielded to the application of ice along the affected side of the face, laid on at periods of five minutes. The pain disappeared in twelve hours, and, after an interval now of ten months, has not returned.—*Med. Press.*

CORRESPONDENCE.

SOME LATE MEDICAL ATROCITIES.

MR. EDITOR,—In your issue of December 6 you use this very significant expression: "Whither are we drifting?" Echo answers, Whither? You have just indulged in a grand scolding of the Board of City Trusts with reference to certain exactions which this grave body desires to impose upon the Medical and Surgical Staff of Wills Hospital for the Treatment of Diseases of the Eye and Ear, in regard to keeping the dispensary open on the Sabbath. I am rejoiced to learn that the staff have rebelled against such a presumptuous assumption of power without any conference upon the subject with the gentlemen concerned, and that you have struck a blow under the fifth rib, so well merited in every case of this kind. Usurpation of trust or power should always be pointedly rebuked. It is high time that the managers of our charities should know how to treat their medical officers; it is too commonly the case that they consider them as their servants, instead of their equals, or superiors: to regard them in any other light than the latter is simply an outrage. Whatever concerns the interests and the dignity of a medical charity is as much the business and the right of the medical and surgical staff as of the Board of Managers, however exalted their social or political status. There should be the most perfect good feeling between the two boards; and any attempt at a display of superiority of the one over the other, or an assumption of power that does not properly belong to either, should be promptly rebuked and discountenanced. The physician is not a servant, but a gentleman; not the subordinate, but the equal, in every essential particular, of any member of any Board of Managers whatever under whom he may hold office.

But I find that I have unconsciously digressed from the subject to which I desire more particularly to call the attention of the reader. I allude to certain recent professional atrocities, of so glaring a nature that it is quite surprising that they should not have received merited rebuke and condemnation. We may well ask, "Whither are we drifting in the practice of our profession?" When Madame Roland was dragged to the scaffold, she was heard to exclaim, "O Liberty, how many crimes are committed in thy name!" and the same language is, I am sure, justly applicable to some recent professional novelties, introduced for the special purpose of torturing human beings and bringing disgrace upon the art and science of medicine and surgery. What, for instance, could be more revolting and diabolical than the insertion of the hand and the whole of the forearm, as high up as the elbow, of a big-fisted son of Æsculapius into a poor woman's bowel, to explore her pelvic organs, or to tickle her solar plexus when she has swallowed an overdose of chloroform or some other narcotic poison? Look for a moment at the operator as he is about to engage in this invention of the devil. He deliberately takes off his coat, rolls

up his shirt and flannel sleeves, oils his limb, and then begins the work of insinuation, expanding first the sphincter muscles of the anus, and then going higher and higher, until his fingers touch the diaphragm, pausing meanwhile to take a full breath, to feel about for something, God knows what, and then tickling, in real earnest, the great sympathetic nerves. Can there be anything more outrageous or more disgusting than such a performance? What necessity is there for such a feat? Cannot the same ends be attained by stimulating applications to the spine, the use of the galvanic battery, flagellation, cold affusions, the insertion of ice into the rectum, and other means? In a case of chloroform-poisoning recently treated by this method, the shameless operator carried his hand four inches above the umbilicus, or a distance of sixteen inches from the anus, and, not content with tickling the diaphragm, ran his fingers against the walls of the abdomen, so that an assistant could distinctly feel them on the outside, and then, as he withdrew the limb, he must needs carry the hand around the uterus and its appendages in search of displacements and fibroid tumors, although such manipulations were entirely foreign to the nature of the case. Then the operator, we are told, as if in ecstasy at his achievement, withdrew his hand, which was not in the "least stained with blood," and found, apparently much to his gratification, that the greatest dilatation of the anus was only ten inches in circumference, corresponding strictly to the size of his delicate forearm. *Jam satis—ohé!*

To Professor Simon, of Heidelberg, belongs the honor of having suggested and first practised this grand operation, "this great advance which this method of exploration has made within a few years past." The word *advance* is certainly well applied here. The process is an *advance*, but not, in this instance, in the *right* direction. Already it counts a number of victims; and, as it is just beginning to attract attention on this side of the Atlantic, we shall soon hear of cases of laceration of the bowel, of fatal peritonitis, and of permanent paralysis of the sphincter muscles of the anus, occasioned by its reckless employment.

The propitious winds have just wafted to us from the other side of the Atlantic an account of another diabolical procedure. Dr. Bouchard, of France, declares that all organic strictures of the œsophagus should be treated by forced dilatation, in the same manner as strictures of the urethra. For this purpose he uses what he terms his *cornual* sounds, the only inconveniences from the employment of which are, it is asserted, the pain and nausea which they produce! It seems that this illustrious savant has had frequent occasion to use this method, and that he has not failed in a solitary instance in restoring the calibre of the œsophagus to a sufficient width, no matter how narrow, hard, or old the obstruction may have been. We cordially congratulate this accomplished surgeon upon his success. It must be a great consolation to this class of sufferers to know that an effectual mode of treatment has at length been discovered for their relief. May we not hope that ere

long some adventurous American surgeon may replace the cornual sound of his French *confrère* with his hand and forearm boldly carried through the stricture into his patient's stomach? We think we already perceive "coming events casting their shadows before them." Would to God that Molière would rise from the dead and assist us in working out these great problems of "advance" in medicine, midwifery, and surgery! "Whither," Mr. Editor, "are we drifting?"

UNGUIS.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, NOVEMBER 13, 1873.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

DR. JAMES TYSON presented a *hydatid cyst* and prepared slides of *echinococci* from the fluid of the cyst and from the germinal membrane lining its interior. The cyst, about one-half inch in diameter, was taken from the anterior border of the right lobe of a *cirrhotic* liver, from the effects of which the patient, a man, aged 32, had died. He had been a drunkard, and was admitted to the Philadelphia Hospital October 4, 1873, with diarrhœa, œdema of the legs, and hydrothorax, but no ascites or jaundice. The limits of the liver's dulness were—in the mammary line, the seventh rib and the free edge of the ribs; in the axillary line, the ninth rib and the free border. Posteriorly, dulness began at the eleventh rib, but the inferior border of the liver could not be determined.

The hydrothorax rapidly increased, and correspondingly dyspnoea. His extremities were always cold, and pulse very feeble. There was no response to remedies, and he gradually grew weaker, dying October 26. Immediately before death dyspnoea was so great from hydrothorax that it was at one time proposed to perform paracentesis thoracis as a palliative; but in his exhausted state it was thought best to omit it. It is likely, however, that his life would have been prolonged some hours at least.

At the *autopsy* fifty-four ounces of fluid were found in the right pleural cavity, and sixteen ounces in the left. The liver, as stated, was *cirrhotic*, weighing two pounds eleven ounces. The other organs were healthy.

A curious fact was observed with regard to the *hydatid cyst*. When removed from the body it was perfectly flexible and membranous, and its walls presented the usual microscopic structure,—layers of transparent homogeneous membrane apparently of albuminous composition, and innermost the germinal membrane with millions of the larvæ attached and falling into the fluid contents of the cyst. The latter was placed in alcohol for preservation, and when removed was found to be hard, exceedingly friable, and breaking under the finger like the shell of an egg.

The *echinococci*, when removed, were perfect spheres with the ring of thirty-four hooklets inverted, and filled, moreover, with what appeared to be granular and globular oil. As the result of osmosis, however, the forms of many had changed, the head being extended and posterior extremity protruded, producing a length of $\frac{7}{8}$ inch, while that of the spheres ranged from $\frac{1}{16}$ to $\frac{1}{8}$ inch. A very marked difference in the appearance of the larva also presented according as the head and row of hooklets were viewed from the front or in profile. In the former instance a mere ring of hooklets

is seen; in the latter a neck-like constriction connects the head or convexity carrying the hooklets with the remainder of the sphere. No cysts were found elsewhere in the abdominal cavity.

Dr. C. B. NANCREDÉ referred to a degenerated hydatid cyst which he had presented through the late Dr. Mustin in 1870. The nature of the cyst was shown by the presence of hooklets, but there were no echinococci.

Dr. R. M. BERTOLET recalled a specimen of multiple hydatid cyst presented by Dr. J. H. Hutchinson, February 23, 1871. In this case there were several cysts in the liver, and a large cyst was found in the connective tissue of the pelvis.

Dr. MORRIS LONGSTRETH said that the remains of this cyst were still preserved in the Museum of the Pennsylvania Hospital, and that the walls had undergone the same peculiar apparently inorganic change on being placed in alcohol.

Dr. BERTOLET said hydatids were very commonly met abroad, and that one could scarcely attend a pathological lecture in any of the larger cities without seeing one or two specimens upon the table among the accumulated pathology of a couple of days. He recalled an occasion on which Professor Virchow had detected with great glee a cyst on the posterior surface of the larynx, which his assistant had overlooked, and remarked, further, that it was the first hydatid cyst he had met in this situation.

Dr. JOHN H. PACKARD exhibited a *specimen of tumor of the humerus*, removed, by disarticulation of the bone at the shoulder, from a patient in the Episcopal Hospital. W. B., æt. 19, the son of English parents who are living and in good health, had always been perfectly well, and had done very hard work at the "squeezer" in a rolling-mill at Pottsville, until about eighteen months ago, when he strained his right arm, and had in consequence an arthritis of the shoulder. This yielded readily to treatment by Dr. J. T. Carpenter, of Pottsville, and he returned to his work. In June last, however, the upper part of the arm began to swell, and became painful, but not severely so except at times; the pain seemed to run down the arm. As the tumor steadily increased in spite of treatment, Dr. Carpenter sent him down to the Episcopal Hospital. On his admission, October 28, the upper arm was the seat of a tumor nineteen inches in circumference; there were in reality two tumors, one beneath the deltoid, and the other, much smaller, at the inner side of the bone. The skin, although deepened in color by repeated blistering, was sound and non-adherent; a good many veins were seen in it. No pulsation, thrill, or *bruit* could be perceived in the tumors. Motion of the joint, whether passive or active, was perfectly free, except as the bulk of the tumors interfered with it. The man's general condition was good.

On the 3d of November Dr. Packard removed the limb at the shoulder, in the presence of Drs. J. T. Carpenter, W. B. Page, and W. R. Cruice, with the resident staff of the hospital. The operation was rendered quite difficult by the close proximity of the outer tumor to the joint; it was done by Larrey's method, the vessels being tied as they were cut, and the inner flap being formed last, so that he could grasp the vessels in its substance until a ligature was placed on the brachial artery. None of the soft tissues external to the periosteum seemed to be in any degree involved. The subsequent course of the case was satisfactory, the man's recovery being uninterrupted.

On making a section, it was found that the adventitious growths had been formed beneath the periosteum, encroaching somewhat on the shaft-walls of the bone by a sort of cupping of its substance, especially perceptible where the tendon of the deltoid was pushed outwards and downwards into a curve. The substance of

the tumors was soft, and so extremely dark as to give at first the impression that they were melanotic; fine spicula of bone radiated outwards through each of them.

A hasty microscopic examination of portions of the adventitious structure, under a magnifying power of about three hundred diameters, disclosed many free nuclei, and nucleated cells of very great variety of shape, but all elongated, and many caudate or bipolar. Unfortunately, the specimen was early placed in a solution of carbolic acid so strong as to destroy its value for further microscopical study.

Except in the age of the patient, and the rapidity with which the new formations progressed, this case corresponds somewhat closely to the descriptions given by various writers of "periosteal sarcoma" or "periosteal osteo-sarcoma."

Pemberton ("Clinical Illustrations of Various Forms of Cancer," p. 74, and Plate III.) gives a case very similar to the one now detailed, but at a more advanced stage, the skin having given way and the tumor having acquired an enormous size.

Bryant ("Practice of Surgery," Am. ed., p. 817) gives a cut of a tumor of the upper part of the tibia, very closely resembling the one in question. He remarks that in proportion to the amount of bony matter entering into the structure of these tumors may they be regarded as innocent, and makes the statement, borne out by the present case, that "the disease is usually seen attacking the ends of the shafts of bones, and not the epiphyses." Wilks ("Pathological Anatomy," p. 35) expresses the same opinion.

Billroth ("Lectures on General Surgical Pathology and Therapeutics," Am. transl. by Hackley, p. 602) says, "Peripheral osteo-sarcoma or periosteal sarcoma (osteoid-chondromata of Virchow) are quite malignant; they either have granulation-structure with osteoid tissue as in osteophyses, and are partly ossified; or they are very large-celled myxo-sarcomata, also partly ossified. The rapidity of their course varies greatly; sarcomata of the lungs have been observed after them."

Gross ("System of Surgery," vol. ii. p. 897) regards these growths as malignant. Erichsen also ("Science and Art of Surgery," Amer. ed., vol. ii. p. 191) speaks of them under the name of "peripheral cancer."

Other writers on surgical pathology speak of these growths, but Dr. P. has found no description more full and accurate than those now referred to.

Dr. J. H. CATHCART presented a specimen of *Fallopian pregnancy, with rupture of the cyst in the third week*. (See Original Communication in current number of the *Times*.)

Dr. JOHN S. PARRY asked how long the lancinating pain had existed in the lower part of the pelvic cavity.

Dr. CATHCART replied that the patient had the pain only on the day she died.

Dr. PARRY said he had asked the question because he considered these periodical pains often of diagnostic value. Physicians have for a long time been unable to diagnosticate with certainty the existence of extra-uterine pregnancies. He thought, however, that there was a series of symptoms which would enable one in the main to predict such a condition. For the space of six or eight weeks after conception there are noted the usual signs of pregnancy, and there are no symptoms of the anomalous condition. After this period, however, the patient will complain of exceedingly severe attacks of pain in the pelvic region, radiating sometimes over the whole abdominal cavity. This is often mistaken for the pain of an uncomplicated cellulitis or pelvic peritonitis, and in a recent case which had come under his observation several physicians of experience had diagnosticated these conditions. This pain is periodical in its occurrence,—every two or four weeks. It is

exceedingly severe, and often produces profound collapse, the patient becoming pulseless, pale, and cold. It is often preceded or accompanied by vaginal hemorrhage in greater or less quantity. The occurrence of these three—1, the usual signs of pregnancy for six or eight weeks; 2, the periodical pain, and 3, the vaginal hemorrhage—ought always to lead the physician to suspect extra-uterine pregnancy. If a deciduous membrane is discharged from the uterus, the diagnosis is certain.

After examining the histories of some two hundred and eighteen cases, he had found the condition was often associated with pelvic peritonitis and malformations about the uterus. In the course of this study he had been surprised to find a large number of cases in which the Fallopian tube entered the cavity of the uterus at some abnormal point, frequently near the cervix instead of the fundus.

In this case the ovum was lodged in the left Fallopian tube, which Dr. P. said was not the most common seat of a tubal pregnancy, it being much more frequent on the right side. The rupture had occurred here much earlier than it usually does, taking place in the majority of cases at the end of the second month. It not unfrequently happens that if it goes beyond this time it reaches nine months, and cases are recorded which have gone beyond full term, the autopsy revealing the fetus in the Fallopian tube. An undoubted decidua lines the uterus in this case, and this is always the case, though this fact is denied by Robert Lee. The decidua is formed and often thrown off, being mistaken for an abortion. Nor is it always thrown off in mass, but often in pieces so small that it can only be detected by careful microscopical examination of the vaginal discharges.

Dr. PARRY also said the second clot in the specimen presented by Dr. CATHCART was the result of a previous hemorrhage; that twin extra-uterine pregnancies were rare, there being but one on record in this country, in the *New York Medical Repository*, in 1810, and possibly one in France.

On the other hand, combined intra- and extra-uterine pregnancies are not so rare.

Dr. H. LENOX HODGE said there had fallen under his notice but one case of extra-uterine pregnancy. It was of the kind called interstitial. The patient was brought to him from the country. The possibility of a tumor being present had been raised on account of the peculiar shape of the body. He decided that it was a case of extra-uterine pregnancy advanced to seven or eight months. In consultation with his father it was determined to bring on labor and endeavor to save both mother and child. This was done by dilating the os uteri with Barnes's dilators. After the dilatation was accomplished, the tissues of the uterus on the side of the tumor were scratched with a blunt-pointed instrument, and finally gave way, and the membranes ruptured. A child was extracted, which lived about three hours, and the mother completely recovered. The seat of the tumor in that instance was on the right side, at the entrance of the Fallopian tube, but the whole uterine cavity was encroached upon by the presence of the child.

Dr. PARRY said that he had met with the record of a case similar to that reported by Dr. HODGE. The patient was delivered by passing the hand into the cavity of the uterus and rupturing the cyst. Dr. PARRY was not certain whether it was tubal or interstitial, and said that he had not met with the record of twenty cases of interstitial pregnancy,—he recalled but eleven out of two hundred and eighteen. Interstitial pregnancy is also more common on the left side than on the right. In a case reported by Braxton Hicks (*Trans. Obstet. Soc. Lond.*, 1868, p. 57), he said the cyst rup-

tured spontaneously into the cavity of the uterus during the sixth month. The placenta was not delivered, and the woman perished.

Dr. HODGE asked Dr. PARRY what he considered the essential difference between *interstitial* and *tubal* pregnancy. He had always considered that interstitial in which the product of conception, though still in the Fallopian tube, had been arrested in that portion passing through the uterine walls.

Dr. PARRY replied that there were a number of theories, some authors defining interstitial pregnancy as does Dr. HODGE, while others believe that the fetus is absolutely developed in the tissue of the uterus, the ovum having entered, when exceedingly small, a crypt which closed over it.

Dr. HORACE WILLIAMS inquired of Dr. HODGE the management of the placenta.

Dr. HODGE replied that it was extracted in the usual manner from the cyst in the walls of the uterus.

The PRESIDENT referred to a specimen of *right tubal pregnancy*, in which the ovum had attained the age of three or four weeks, presented to the Society by Dr. Harris in 1857.

The PRESIDENT also recalled a specimen which he had presented some years ago, in which, during menstruation, a follicle in the ovary had ruptured, and hemorrhage had occurred from the corpus luteum. Acute peritonitis supervened, and proved fatal in forty days.

Dr. TYSON also exhibited the *lungs* of a man who had died of *acute miliary tuberculosis* in his wards at the Philadelphia Hospital. He was 32 years of age, and had been employed in the gas-works of this city. His father died of typhus fever, and his brothers and sisters were in good health, but the cause of his mother's death is unknown. He had himself never been ill, except as to a slight cold last winter.

On admission, October 25, he said he had been sick four weeks. For the first two weeks he complained chiefly of malaise, and at the end of that time had a chill followed by fever, with diarrhœa and some cough, and with these latter symptoms he kept his bed.

When examined after admission, there was a circumscribed red flush on each cheek; his skin was moist; temperature 100° Fahr. There were slight tenderness in the right iliac region, slight diarrhœa, some sore throat, and bronchial cough with expectoration of mucus.

By percussion there was resonance throughout the chest anteriorly and posteriorly, with symmetrical expansion throughout. In auscultation no râles were heard; the respiratory murmur was not enfeebled, being somewhat louder than in health. The increased vocal fremitus and vocal resonance were, however, marked, but, being unaccompanied by any other signs of chest-trouble, this peculiarity was accepted as a physiological exaggeration in this individual.

By the 28th the diarrhœa had ceased, while the cough increased, with expectoration of a "currant-jelly"-like matter. His temperature on this day in the morning was 99° Fahr., in the evening 99½° Fahr.

On the 29th the morning temperature was 100¼° Fahr., with a pulse of 110; in the evening 103° Fahr., with a pulse of 120.

30th.—Temperature 101°, pulse 111; evening, temperature 101°, pulse 100.

31st.—Temperature 100½°, pulse 92; evening, temperature 100½°, pulse 88.

On November 1 he was weaker, and there was some disturbance of the nervous system, indicated by muttering delirium from which he could be roused, subsultus, jerking of the hands and feet, and dilatation of the pupils. The temperature in the morning was 100½°, in the evening 100½°.

On the 2d, morning temperature 101°, evening 100½°.

On the 3d, fine crepitus was heard throughout the right lung, and there was more of a bronchial element in the breathing, but the physical signs were otherwise unchanged.

By the 5th he was much weaker; crepitus was heard over both lungs, and resonance was slightly impaired below the scapulae, but there was no dulness.

On the 7th occurred a profuse sweat, with marked reduction of temperature, from 100° in the morning to 97° in the evening. This was repeated the next day, with the same difference in evening and morning temperature, and again on the 9th. The sweating was particularly profuse about the head, and twice on this day, on the evening of which he died, he uttered a sharp cry.

At the post-mortem examination both lungs were found studded with gray granulations about the size of a millet-seed, so closely strewn that not a square inch of lung-tissue escaped. The pleura and bronchi beneath the mucus-membrane were thickly studded with small shining granulations of miliary tubercle. The larynx was not examined. There was a small cavity an inch in diameter in the posterior apical portion of each lung. They were apparently empty, their walls were thickened and smooth, and they had evidently existed some time. The bronchial glands were enlarged, but not softened.

The heart was healthy, but the pericardium contained some small patches of old lymph.

The peritoneum and mesentery were normal, but there was considerable congestion of the lower part of the ileum and upper part of the colon: there was no ulceration. The liver and kidneys were fatty.

On exposing the brain there appeared considerable subarachnoid oedema over the cerebrum. Ten ounces of serum were found in the base of the brain and beneath the tentorium, but little in the ventricles. A deposit of miliary tubercle was found upon the upper surface of the cerebrum, the cerebellum, on the pons, and the choroid plexus was studded with tubercle.

Dr. HUTCHINSON referred to a case of acute miliary tuberculosis supervening upon chronic pleurisy, reported by him at length in the *Philadelphia Medical Times* for March 1, 1872. The most noticeable feature of the case was the want of correspondence between the physical signs and general symptoms. Thus, while the patient suffered from extreme dyspnoea, there was only slight dulness upon percussion over the back of the chest, and auscultation revealed nothing more than a diminished intensity of the respiratory sound, together with prolongation of the expiratory murmur, and occasional sibilant and sonorous râles. There was, however, cyanosis of the lips and of the ends of the fingers, showing interference with the circulation through the lungs. The temperature was elevated, but the evening rise was exceedingly slight. Taking this circumstance and the negative signs furnished by the case into consideration, he was able to make a correct diagnosis during the life of the patient.

The PRESIDENT said that in his experience the results of auscultation in these cases had been uncertain and irregular. He had not observed marked suppression of vesicular murmur; but more generally alteration of the murmur, the expiration being prolonged, and the inspiration at times rude, at others hissing, with, at a comparatively early period, the occurrence of diffuse, fine crackling.

DEVELOPMENT OF BACTERIA.—Dr. Oslez, of Canada, claims to have witnessed, under the microscope, the actual development of bacteria from small masses of agglutinated corpuscles. To observe this phenomenon, the blood is mixed with a weak solution (three-fourths per cent.) of common salt, and maintained at the temperature of the body.

GLEANINGS FROM OUR EXCHANGES.

SUICIDES IN FRANCE.—The Paris correspondent of the London *Lancet* extracts from the *Journal Officiel* the following figures: During the year 1871, 4490 acts of suicide were accomplished; 3596 by men, and 894 by females. Out of the above number of cases, 164 individuals had not attained their majority; 1125 were aged from twenty-one to forty; 1782 from forty to sixty; 1362 above sixty; whilst the age of fifty-seven among them was unknown. As to the married or single condition of 4324 of the individuals who had committed suicide, and concerning whom authentic information could be gathered, the following figures are given, and are of great interest: 1410 single people; 1443 married with children; 676 married without children; 484 widows and widowers with children; 311 widows or widowers without children. More than six-tenths (2699) inhabited rural communes with a population of not more than 2000 inhabitants, whilst 1723 inhabited towns. Another interesting item is the mention of the peculiar manner in which death was brought about. Thus, it appears that out of the total number of 4490 cases of suicide, in 1991 it was produced by strangulation; in 1278 by drowning or submersion; in 591 by gunshot wounds; in 215 by asphyxia with coals; in 152 by cutting instruments; in 143 by a wilful fall from heights; 70 by poison; 50 by various other means. As to the supposed motives which led to the committal of suicide, in only 4077 cases was the cause made out. In 1472 cases suicide is attributed to mental disease; in 950 to anguish or pain of various kinds (out of which 535 to physical pain); 651 to bad conduct (out of which 492 to drinking); 620 to family griefs; and 369 to misery. In fifteen cases suicide was committed by the authors of great crimes.

ICTERUS AFTER THE ADMINISTRATION OF HYDRATE OF CHLORAL (Dr. A. Wernich, *Deutsches Archiv für Klin. Med.*).—Reports of cases of icterus following the administration of chloral have already been published both by Dr. Wernich and by other observers; and to these he wishes to add those contained in the present article, in the hope that physicians using this drug may be induced to contribute their observations, and thus aid in the accumulation of sufficient data to afford an explanation of its influence in producing icterus.

Case I.—A woman, the wife of a laborer, æt. 37, had been suffering for a year from indigestion, and at times vomiting, and for twelve weeks from severe pain in the right hypochondrium. For five days previous to her admission into the hospital she had noticed a yellowish color of the skin and conjunctiva, and that her urine was of a dark color. In the epigastric and right hypochondriac regions there could be felt a tumor of firm consistence almost as large as a man's head, which by palpation and percussion was found to be sharply defined from the liver.

During the ensuing two weeks the icteroid hue of the skin was but slight, and the size of the tumor steadily but slowly increased. These symptoms were accompanied by paroxysmal attacks of pain, the severity of which constantly increased, which at first were to some extent relieved by large hypodermic injections of morphia. Later, however, morphia ceased to afford relief, and a trial of chloral was made. The patient passed a quiet night, but in the morning was found in a state of stupor, and the surface of the entire body was of an olive-green color. This continued for two days, accompanied by a mild delirium until the death of the patient, ten days later.

Case II.—A woman, æt. 34, had suffered for three years from want of appetite, vomiting, and a slight de-

gree of jaundice. Paroxysmal attacks of pain came on, the intensity of which steadily increased, and, as morphia failed to give relief, chloral was given, with results similar to those of the first case. The following morning the skin was found deeply jaundiced, the patient was sleepy, and there was some mental disturbance. Death followed the next day.

Case III.—A woman, æt. 40, had mitral insufficiency of high grade, and suffered from results consequent upon that affection. To relieve her from the sufferings due to hydrothorax, after the failure of diuretics resort was had to paracentesis, which afforded temporary relief. The sufferings of the patient during the night being very great, morphia was administered, but with no good effect. Chloral was given and sleep produced. On the following morning the entire body was of an olive-green color, and the patient complained of unpleasant sensations about the head. The jaundice continued until the death of the patient, which occurred about two weeks later. The urine in this case was scanty, and contained albumen, but no biliary coloring-matters. The dose of chloral given in each of these three cases was three grammes.

Dr. Wernich considers that all the suggestions that have been made in explanation of this result of the administration of chloral are unsatisfactory. He concludes also that as yet no rule can be laid down to govern the exhibition of chloral in cases in which hepatic disease exists, for although in the cases narrated the administration of chloral seemed to promote the appearance of the icterus, yet it is often given without injury to those having affection of the liver, either active or latent.

MISCELLANY.

JACOB'S food for children is prepared as follows: Crack a teaspoonful of barley in a common coffee-mill, then boil it fifteen minutes in a gill of water, adding a pinch of salt. Then strain, and for a young child add one-half as much cow's milk as you have barley-water, and, whilst tepid, nurse from a nursing-bottle. Sweeten lightly with sugar. If the bowels are costive, use oatmeal in place of barley. Keep the bottle clean.

HORSE-MEAT appears to have acquired permanent footing in the popular Austrian bill of fare. According to the *Neue Freie Presse*, the slaughter of horses for food in July last amounted to 203, in August to 184, and in September to 221. In the entire quarter no less than 608 horses were converted into food. The price is not exorbitant. The "fore-quarters" sell at from twelve to fourteen kreutzers per pound, the hind-quarters at from fourteen to sixteen, the ribs and loins from sixteen to eighteen. Fat sells at from eighteen to twenty-six florins the hundred-weight, and bones at one florin and thirty kreutzers.

FATAL POISONING BY COLCHICUM.—Seven persons have died, and five others remain in a precarious condition, in Montreal, poisoned by colchicum. It appears that a man named Flaherty, seeing a sleigh standing on the street without a driver, stole a bottle of what he supposed to be sherry therefrom, but which proved to be wine of colchicum. This he shared with the inmates of the tenement in which he lived, and some neighbors, with the fatal results mentioned.—*The Canadian Medical Journal*.

NOTES AND QUERIES.

BLUE PUS.

CAN some of the readers of the *Times* give me some particulars on the subject of blue pus? A patient of mine with laryngeal chondritis discharged an abscess recently by cough, and among the bloody débris, but distinctly apart from it, were some two or three drachms of thin greenish-blue pus. Dr. Bertolet made a microscopic examination of this pus, and kindly wrote me as follows:

"The blue pus contained blood and pus-corpuscles, epithelial scales, and shreds of yellow elastic tissue. No vibriones or fungi are contained in this sputum. Although having a remarkable blue color *en masse*, this was not perceptible under the microscope. By this time the sputum itself has assumed a dark brownish-red color. . . . You will find this subject very well worked up by Lücke in *Archiv f. Klin. Chir.*, Bd. iii. p. 135; also by Zaufal, in *Archiv f. Ohrenheilk.*, vol. vi. pp. 206-219, upon 'Blue Pus in Otorrhoea.' The former attributes the blue color to the presence of vibrios, the latter to bacterium termo. Neither were present in this specimen, so that it is at least plausible to suppose that the blue coloration is due to the putrefactive changes acting upon the hæmatin or sulphate of iron."

Dr. Gibb, of London, presented a communication to the British Medical Association, at their late meeting, entitled "Cyanopuon Laryngis," but, from my recollection of the perusal of the published abstract of that paper, I cannot draw any satisfactory conclusion as to the appearance of this pus in my own case.

The one discharge of this peculiar pus has been the only one, though the patient has been expectorating ordinary purulent matter for a month since.

The presence of the blood-corpuscles detected by Dr. Bertolet may be accounted for by the pus having been in the basin in contact with a little blood, expectorated when the abscess ruptured. I am unable to determine the location of the abscess, but am inclined to believe that it is connected with the cricoid cartilage.

Any information on this subject, communicated personally or through the medium of the *Times*, will be greatly appreciated.

J. SOLIS COHEN.

THE next conversational meeting of the Philadelphia County Medical Society will be held at the Hall of the College of Physicians, Wednesday, December 24, 1873, at eight o'clock P.M.

The subject for the evening will be "Tracheotomy in Pseudo-membranous Croup," and the narration of a successful case. To be opened with remarks by Dr. M. O'Hara.

All regular practitioners of medicine in the city are cordially invited to attend.

At a conversational meeting of the Philadelphia County Medical Society, held December 10, 1873, Dr. J. G. Stetler presented the following resolutions, which were unanimously adopted:

"Whereas, It has pleased Providence to remove from our midst Dr. William Mayburry whilst still in the vigor of life and usefulness: therefore, be it

"Resolved, That the Philadelphia County Medical Society has heard with unfeigned regret of the demise of our late fellow-member and one of its honored ex-presidents.

"Resolved, That in the death of Dr. Mayburry this Society, as well as the profession at large, has lost an active and valuable co-worker: one who has always stood up for the elevation, rights, dignity, and ethical honor of the profession.

"Resolved, That we hereby tender our sympathy and condolence to the bereaved and afflicted family for this severe dispensation of Providence.

"Resolved, That a copy of the preceding preamble and resolutions be transmitted to the family of the deceased."

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 16, 1873, TO DECEMBER 22, 1873, INCLUSIVE.

BAILY, E. J., SURGEON.—Granted leave of absence for three months. S. O. 249, A. G. O., December 18, 1873.

CALDWELL, D. G., ASSISTANT-SURGEON.—Assigned to duty at Fort Griffin, Texas. S. O. 222, Department of Texas, December 6, 1873.

CAMPBELL, A. B., ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of Texas, for assignment to duty. S. O. 247, A. G. O., December 13, 1873.

STYER, CHARLES, ASSISTANT-SURGEON.—Leave of absence extended twenty days. S. O. 67, Division of the South, December 16, 1873.

SATURDAY, JANUARY 3, 1874.

ORIGINAL COMMUNICATIONS.

ON WHAT WAS FOUND IN THE ALIMENTARY CANAL OF LUCIOPERCA.

BY HENRY C. CHAPMAN, M.D.

TO the naturalist no family of animals is more interesting than the entozoa, while to the physician some knowledge at least of this subject is of practical importance. The physiologist observes in these animals nutrition carried on without a stomach or intestines, which were so long regarded as absolutely necessary to the maintenance of animal life; while the embryologist sees in the generative organs a true hermaphroditic structure, and has constantly the opportunity of readily following the development of an animal from the state of the egg to that of the adult. By such investigations the ravages of trichiniasis have been checked, and the possibility of eradicating diseases like *stagers* and hydatids has been demonstrated. Naturally, therefore, when the opportunity presents, the viscera should be carefully examined for entozoa, so called in contradistinction to the epizoa, or those parasites which live externally. Sometimes little or nothing new is discovered; occasionally a new species appears; while nearly always some object of interest rewards the labor bestowed. Thanks to Mr. Francis Wistar, of Duncannon, Pa., I had the opportunity of dissecting the so called pike perch, or *Lucioperca*, a member of the Percoid family of fishes, often erroneously known as the Susquehanna salmon. Opening the stomach, intestine, and cæcal appendages, I found them filled with worms. I transmitted the viscera containing the worms to Dr. Leidy, who kindly determined for me the genera and called my attention to many interesting points in their economy. Before noticing the worms, it seems proper to mention here that Dr. Leidy discovered also in the stomach of the fish the valve of a *Lingula*, a marine shell-fish never found north of North Carolina: this is a very interesting fact, and important in reference to the habits of the fish, which has always been supposed to be confined to fresh waters, and not migratory. The only explanation, however, of the finding of the shell in the stomach, is that the fish swallowed it near the North Carolina coast and then went northward. The worms infesting the viscera of animals are either flat or round, called by helminthologists Plathelminthes and Nematelminthes; the tape-worm or *Tænia* will serve to represent the first order, the *Trichina* the second. Every one is more or less familiar with the general form of the *Tænia solium*, or tape-worm of man,—a long worm exhibiting an expanded head, with four suckers and a circlet of hooks, a slender neck composed of narrow segments or joints, a body in which the joints are broad and much flattened, the posterior ones containing the generative apparatus; each segment contains a male and a female organ, which are self-impregnating, an instance of true

hermaphroditism. At the margins of the joints may be seen the apertures through which the penis protrudes or the eggs escape. The position of these apertures is important as a means of determining the genus: thus, in the *Bothriocephalus* or *Tænia lata* the apertures are in the middle of the broad surface of the segments. The tape-worms in our *Lucioperca* belong to this genus, and are probably a new species. The tape-worm nourishes itself by simply imbibing the juices in the alimentary canal of the animal in which it lives. For a long time the origin of the tape-worm was involved in great obscurity; the cause of this was due, no doubt, to the fact of the tape-worm passing its embryo phase in one animal, its adult stage in another. Indeed, these different stages of existence were formerly supposed to be distinct animals, and described as such. Thus, the *Tænia solium* of man is found in its embryo condition in the muscles of the pig; at this stage of its existence it is known as the *Cysticercus cellulosus*, and its presence gives rise to measly pork. Should some of this measly pork be eaten raw or partially-cooked by a human being, the embryo *Tænia* or *Cysticercus*, finding in the intestine proper nourishment, develops, joint after joint is added, until finally the *Cysticercus* becomes a *Tænia*. In the segments most remote from the head, as before stated, are seen the generative organs, in which are found the eggs. These joints are passed off from time to time with the fæces, which are eaten by pigs; in the stomach of these animals the eggs develop into minute spined embryos; these migrate from the stomach and reach the various tissues, where they are transformed into *Cysticerci*. The *Tænia mediocanellata*, which differs from the *Tænia solium* in not having the circlet of hooks in the head, as well as in other characters, is derived from raw beef, which often contains the *Cysticercus* of that tape-worm. The disease in sheep known as *stagers* is due to the presence in the brain of the *Cœnurus cerebri*; the *Cœnurus* becomes in the intestines of the dog a tape-worm. The hydatids known as *Echinococci* are also only undeveloped tape-worms. The *Cysticercus* of the rat in the alimentary canal of the cat becomes a *Tænia*. As yet the *Cysticercus* of the tape-worm of our *Lucioperca* is unknown. These names—*Cysticercus*, *Cœnurus*, *Echinococcus*—ought to be discarded, since they only confuse, giving the idea that these organisms are distinct animals, whereas they are only the young of different *Tæniæ*. In reference to this matter there is an interesting fact in the literature of helminthology, not generally known, and not alluded to by Cobbold, which makes part of the true history of the development of the *Trichina*. In 1836 Professor Owen described the *Trichina spiralis* in man; in 1846 Dr. Leidy gave an account of the *Trichina spiralis* he found in the pig. Professor Leuckart,* as he acknowledges in his work, availed himself of Dr. Leidy's discovery by

* Untersuchungen über *Trichina Spiralis*, 1860, p. 18. "Eingedenk der Angaben Leidy's nach denen *Trichina Spiralis* gelegentlich auch in den Muskeln des Schweines gefunden werden konnte Ich in der Wahl des Versuchthieres kaum zweifelhaft sein."

using the pig in his investigations on Trichiniasis in 1860, and demonstrated that the Trichina of the pig when taken into the intestines of man laid eggs which developed embryos, and that these migrated into the tissues of the individual who had eaten the raw pork,—a common custom in Germany. Two genera of round worms, of which the Trichina is an example, were found in the alimentary canal of our pike perch. One of these was an Echinorhynchus, —the bristly-snout worm, so called from the snout being provided with bristles. The other genus was a Nematoid, as yet not investigated. The Ascaris, or thread-worm of the human body, is a familiar example of a Nematoid.

Man usually assumes that the world was made for him, forgetting that when the axe of civilization is heard there die out the most beautiful birds, brilliant insects, lovely flowers, and other bright forms that enchant the eye of the wanderer among tropical forests. If the nervous system of the tape-worm and Trichina were as much developed as that of man, and they reasoned after his manner, they would at once conclude that many animals were made for them; for are not the rabbit and dog the homes of the *Tænia serrata*, the rat and the cat necessary to the existence of the *Tænia crassicolis*, while the pig and man—the lord of creation—are only the dwelling-places of Trichina, *Tænia*, and other worms?

A CASE OF IMPREGNATION WITHOUT INTROMISSION.

BY THOMAS HAY, M.D.,
Philadelphia.

THE following case is interesting as illustrating the fact that impregnation can take place without intromission. It shows, too, that a persistent hymen is no evidence in a case of rape.

In this case the semen was expended on the external parts, and the spermatozoa, by their peculiar motions, through affinity or attraction, found their way into the uterus, and came in contact with, and fecundated, the ovum.

I was visited by Mr. and Mrs. G., from New Jersey, in consequence of enlargement of the lady's abdomen. A belief was induced that a tumor from disease had made its appearance, and that it was growing inside.

This belief was strengthened and almost confirmed by the fact that the existence of pregnancy was not thought possible, and such opinion was not entertained in her case. She had been married more than four months, there *never was intromission*, and the *courses appeared regularly as usual*.

The husband was aware of the presence of an unyielding obstacle, and the severe pain at coition made penetration impossible. Modesty and other reasons caused delay in seeking medical advice till the already enlarged abdomen was increased in size, and the pain during intercourse had become so great that it was no longer attempted.

Examination showed a strong, unyielding hymen, attached all round the vagina *near its entrance*, hav-

ing a hole above the middle large enough only to admit the tip of the little finger; a vascular tumor of the urethra, and extensive erythema of the vulva; the parts were irritable, and the touch of the finger caused the patient to cry out from pain.

I made a crucial incision into the hymen, cut off the four angular flaps, excised the vascular tumor, and applied caustic.

The opening made was maintained by cylinders of lint. The pelvic cavity was normal, and the parts soon healed.

The lady had been three months pregnant, and, as the signs of pregnancy increased, she, as well as the husband, became better satisfied with my diagnosis; and when, after about six months, she was delivered of a healthy, well-developed boy, both were convinced of its correctness, and, as indulgence in the connubial privilege was no longer a cause of pain, they were quite happy.

MEMORANDA OF THE EFFECTS OF CARBOLIC ACID IN A LARGE DOSE.

BY S. J. RADCLIFFE, M.D.,
Washington, D.C.

GENERAL H., a retired officer of the army, had been suffering from an attack of chronic articular rheumatism. On the 27th of November I prescribed for him an effervescing saline draught, consisting of eight ounces of a carbonated solution, and an acid solution containing one ounce of citric acid and eight ounces of water,—half an ounce of each to be taken while effervescing.

I visited him on the morning of the 28th, and found him sitting on the bed, a vessel at the bedside one-third filled with matter, probably about a pint, seemingly from the stomach, mixed with blood. On inquiring what was the matter, he replied he had been vomiting, and his nose had been bleeding. He said he had taken, a little while before my visit, the first dose of the medicine prescribed, and it did not effervesce as I had said it would, but made him very sick, and he threw it up with the contents of his stomach, and his nose bled quite freely immediately after. On tasting the mixture in the vial containing the acid solution, I at once recognized the flavor, and informed the general that he had taken a pretty good dose of carbolic acid, the odor of which he then for the first time remembered. I took the vial containing the acid solution to the drug-store, and the drug clerk admitted confusedly, after seeing the prescription again, that he had made the mistake and put an ounce of fluid carbolic acid in eight ounces of water, instead of an ounce of citric acid. There was about half a drachm of the acid in each dose, the quantity the patient took. Fortunately for him, he took it on a full stomach, after breakfast, or it would doubtless have produced disastrous results. As it was, he experienced no other effects than nausea, epistaxis, some drowsiness, and a bad taste in the mouth during the day.

REPORT ON THIRTY CASES OF CHOREA.

BY GEORGE S. GERIARD, M.D.,

Assistant Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases.

THE majority of the following cases of chorea were obtained from the records of the department for nervous diseases connected with the Ortho-

pedic Hospital; for the data of the remainder I am indebted to Dr. Mitchell, who very kindly placed his private case-books at my disposal.

So far as I have been able to discover, this is the first collection of cases of chorea that has been made in this country.

I have arranged the cases in a tabular form, in order to facilitate analysis.

NO.	SEX.	AGE.	SIDE AFFECTED.	DURATION OF COMPLAINT BEFORE TREATMENT.	APPARENT EXCITING CAUSE.	MODE OF ONSET AND SEASON OF YEAR.	PREVIOUS ATTACKS.	PECULIARITY OF SYMPTOMS.	TREATMENT.	RESULT.	ADDITIONAL REMARKS.
1	M.	8	Right.	From infancy.	Followed infantile convulsions.	Sudden.	Partial right hemiplegia, and carpo-pedal spasm.	Arsenic; division of tendo-achillis and plantar fascia-apparatus.	Marked improvement.	
2	F.	16	Entire body.	Fifteen years off and on.	Fright.	Gradual.	Galvanism; arsenic.	Marked improvement.	Twenty-drop doses of Fowler's solution taken without toxic effects.
3	F.	9	Entire body.	Three weeks	Fright.	Gradual; summer.	Patient exceedingly irritable.	Arsenic; zinc.	Cure.	
4	M.	17	Right.	Three m'ths	None discovered.	Gradual.	Loss of power in right arm and leg; attacks of "petit mal."	Bromide and iodide of potassium.	Unknown.	
5	M.	16	Entire body.	Ten years.	No assignable cause.	Gradual.	Loss of power in some of the facial muscles.	Galvanism; zinc.	Cure.	
6	M.	7	Entire body.	Six weeks.	None discovered.	Gradual.	One previous attack.	Movements very violent.	Arsenic; cold douche; chloral occasionally at night.	Cure.	
7	F.	8	Both arms, head, and neck.	Four months	Rheumatism	Gradual.	A slight previous attack.	Harsh systolic apex murmur; loss of power in left arm and leg.	Arsenic; cold douche.	Marked improvement.	
8	F.	4	Both sides, but right chiefly.	Three m'ths	None discovered.	Spring.	Loud noise during respiratory movements.	Cimicifuga; arsenic.	Marked improvement.	
9	M.	12	Head and shoulders, and occasionally the face.	Five months	No assignable cause.	Both attacks occurred in the spring.	One previous attack.	Patient exceedingly irritable.	Arsenic.	Cure.	
10	F.	16	Right.	Six years.	Fright.	Autumn.	Systolic apex murmur.	Arsenic.	Not known.	
11	F.	22	Right.	Nine years off and on.	Fright.	Bromide of potassium; arsenic; iron.	Cure.	
12	F.	17	Both sides, but chiefly the right.	Two weeks.	Violent and long-continued tooth-ache.	Winter.	Arsenic; cold douche.	Cure.	Patient's mother had chorea early in life.
13	F.	9	Right.	Eight weeks.	Fright.	Gradual, and preceded by pain in arm.	Slight loss of power in right leg.	Zinc; arsenic; cold douche.	Great improvement.	
14	F.	15	Right.	Ten months.	Fright.	Sudden; spring.	Loss of power in right arm and leg.	Zinc; douche.	Cure.	
15	F.	7	Entire body.	Four weeks.	Violent abdominal pain	Spring.	Arsenic; purgatives.	Cure.	
16	M.	8	Left.	Three weeks	Rheumatism	All of the attacks occurred in the spring.	Two previous attacks.	Murmur of mitral regurgitation.	Arsenic; iron.	Cure.	
17	M.	14	Head and right arm.	Two weeks.	Fright.	Spring.	One previous attack.	Zinc.	Marked improvement.	
18	F.	16	Left.	Two months	Suppression mensium.	Spring.	Arsenic.	Cure.	
19	M.	8	Right.	Three years off and on.	Rheumatism	Winter.	Loss of power in legs.	Murmur of mitral regurgitation.	Syr. ferri iod.; ol. morrhue.	Improvement.	
20	F.	17	Left.	One month.	Rheumatism	Sudden; spring.	Soft basic systolic murmur.	Arsenic; chloral.	Improvement.	
21	F.	16	Entire body, but chiefly right side.	Three years off and on.	None discovered.	Iron; arsenic.	Left off attendance.	Neurotic family history.
22	F.	9	Entire body, but chiefly left side.	Eight m'ths.	None discovered.	Spring.	Sulphate of zinc.	Not stated.	
23	F.	14	Left.	Two months	Uterine irritation.	Some loss of power in left side.	Arsenic; atropia.	Marked improvement.	

NO.	SEX.	AGE.	SIDE AFFECTED.	DURATION OF COMPLAINT BEFORE TREATMENT.	APPARENT EXCITING CAUSE.	MODE OF ONSET AND SEASON OF YEAR.	PREVIOUS ATTACKS.	PECULIARITY OF SYMPTOMS.	TREATMENT.	RESULT.	ADDITIONAL REMARKS.
24	F.	14	Left.	Ten days.	Mental worry.	Sulphate of zinc; douche; arsenic.	Cure.	One sister had chorea.
25	F.	11	Right.	One year.	Hard study and mental worry.	Summer.	Loss of power in right arm and leg.	Arsenic.	Improvement.	Neurotic family history.
26	F.	13	Right.	Six weeks.	Blow upon hand.	Summer.	Sulphate of zinc.	Cure.	One sister attends hospital for epilepsy.
27	F.	4	Entire body, but chiefly the left.	Two weeks.	No assignable cause.	Gradual; spring.	Movements very violent; loss of power in right side.	Arsenic; douche; cimbicifuga.	Cure.	
28	F.	10	Entire body.	No assignable cause.	All attacks occurred in the spring.	Three previous attacks.	Child became very pert.	Arsenic.	Cure.	
29	M.	18	Right.	No assignable cause.	Both attacks occurred in the spring.	One previous attack.	Gymnastics.	Cure.	
30	M.	7	Entire body.	One month.	Mental distress.	Summer.	Curious forward and backward movement.	Zinc; arsenic; douche.	Cure.	

In reviewing the preceding table, we find in regard to the age and sex of the patients that there were—

Under 10 years of age 12 cases: 5 males 7 females.
 From 10 to 21 " 18 " 5 " 13 "

Total 30 cases: 10 males 20 females.

This table agrees with the common observation that chorea is essentially a disease of early life, and that females are more prone to the disease than males.

In the second period of the summary the number of females is more than twice as great as the number of males,—a disproportion which may be accounted for by the fact that the period mentioned embraces the age of puberty, when the female is especially liable to disturbances of a nervous kind.

In fifteen cases the affection was entirely unilateral, the irregular movements being confined in ten instances to the right side, and in five to the left. In seven cases the choreic movements were stated to have been general; in three to have been general, but particularly marked upon the right side; and in two cases to have been general, but chiefly pronounced upon the left side. In the remaining two cases the movements were confined to certain groups of muscles.

According to M. Sée, the irregular movements of chorea ordinarily predominate on the left side. Dr. James Russell, on the contrary (*A Contribution to the Clinical History of Choreia, Medical Times and Gazette*, 1868 and 1869), found in twenty-nine cases in which the disease was unilateral that the irregular movements were confined in eleven instances to the left side, and to the right in eighteen. Dr. Hughlings Jackson states that the side (as in hemiplegia from embolism) usually affected is the right.

Dr. Russell states that many cases of chorea commencing unilaterally ultimately become bilateral. As an illustration of this point, the following case may be related:

Jane McC., æt. 4, was seen for the first time on the 25th of May, 1873, about one week after her mother had first observed twitchings of the muscles of the left side of the face and of the left arm. The irregular movements had gradually become more violent, and had extended to the left leg, but not to the right side of the body. The patient was ordered to have cold affusions to the spine night and morning, and to take arsenic in increasing doses. On the 28th the movements had extended to the right side, and were almost as violent as upon the side first affected. The child finally recovered, but her convalescence was prolonged by partial left hemiplegia.

In regard to the alleged cause of the disease, it will be seen from the table that it was ascribed to fright in seven cases; to rheumatism in four; to violent pain in three; to mental worry in three; to uterine irritation in two; to infantile convulsions in one: total, twenty. In the ten remaining cases no cause was discovered.

This table shows, what is in accordance with clinical experience, that fright and rheumatism are frequent causes of chorea. Cardiac murmurs were found in the four cases in which rheumatism was presumed to have been the exciting cause of the complaint. Dr. Kirkes maintained that when a connection between rheumatism and chorea is found to exist there has been an inflammation of the valves of the heart, and that the association is not between chorea and rheumatism, but between chorea and valvular disease of the heart.

Of the many theories that have been advanced by writers on chorea to account for the connection of the disease with a cardiac lesion, there remains but one—the theory of embolism—which has not been abandoned as untenable.

In the majority of the cases in which fright was the assigned cause of the disease, there was an interval of some days or even weeks between the exposure to the cause and the development of symptoms. In a few instances, however, there was an immediate outbreak of choreic movements. In Case 10, a girl ten years of age, irregular movements began almost

immediately after the patient had been frightened by having a dead cat flung at her.

In two of the cases in which no exciting cause could be found there existed a distinctly neurotic family history. In three cases, all females, aged seven, eleven, and fourteen, respectively, the choreic movements followed prolonged mental efforts on the part of the patients to take a good standing in their classes at the July examinations. I have recently heard of three other cases in which chorea was developed under similar circumstances.

Dr. Mitchell has observed that chorea occurs more frequently, and in a more severe form, in the spring than at any other season of the year. He has also found that the attacks of epileptics, besides being of more frequent occurrence in the spring, are much more difficult to control than at other seasons.

A glance at the table will show that the attacks occurred in the spring in thirteen cases; summer, four; autumn, one; winter, two: total, twenty.

In the ten remaining cases the point is not mentioned. It is difficult to offer any explanation for this remarkable preference of chorea for the spring months, unless it is due to the enervating weather of the season in question. Of seven cases in which previous attacks had occurred, five had had one previous attack, one had had two, and in the seventh case the patient had suffered from three. All but one of these previous attacks had occurred in the spring; and the tendency that chorea has to recur at this season is thus very well shown.

The presence of partial paralysis of some kind was noted in nine cases. Out of this number five had right hemiplegia, two had left hemiplegia, and of the remaining two cases there was loss of power in some of the facial muscles in one instance, and in one leg in the other. The frequent occurrence of unilateral chorea, and of "choreic hemiplegia," unquestionably gives much support to the theories advanced by Drs. Hughlings Jackson and Broadbent in regard to the seat of the lesion of the disease. Dr. Jackson (*Edinburgh Medical Journal*, 1868) has gone so far as to localize the seat of the lesion in the "convolutions near the corpus striatum."

Dr. Broadbent (*British Medical Journal*, 1869) is of the opinion that the lesion is situated in the sensori-motor ganglia; and he thinks that the phrase "delirium of the sensori-motor ganglia" is more applicable to the disease than "insanity of the muscles." In regard to the nature of the lesion, Dr. Jackson is disposed to believe exclusively in embolic obstruction of the smaller branches of the middle meningeal artery. In answer to the often-urged argument against embolism being the cause of chorea, that anæmia from plugging of vessels can scarcely lead to increased expenditure of force, Dr. Jackson quotes the conclusion arrived at by MM. Cotard and Prévost, that "obstruction of arteries is ordinarily followed by hyperæmia," etc.

Dr. Broadbent holds that the symptoms characteristic of chorea arise not from any peculiarity of the morbid change, but out of the function of the particular centres affected.

Both of these writers agree in laying much stress

upon impairment of nutrition causing "instability" of the part affected, as opposed to destruction of function. The presence of anæsthesia or of disturbance of the special senses was not noted in any of the cases contained in the table, and it may be stated in this connection that Dr. Mitchell examined the eye-ground in a number of instances, but the results were always of a negative character.

It will be seen from the table that the main treatment of the disease in the majority of cases consisted in the administration of arsenic. This metal was generally exhibited in the form of Fowler's solution, and the doses, small at first, were gradually increased until slight toxic effects were produced. On the occurrence of constitutional symptoms the patients were directed to gradually reduce the doses of the medicine, and then to increase them again. In the more obstinate cases arsenic was pushed to its full toxic effect. Zinc in the form of sulphate was employed in a number of cases, and with a result almost as good as that following the use of arsenic. The mode of its administration was much the same as that adopted in the case of arsenic: that is, in doses gradually increased. In the majority of instances, in addition to the medicinal treatment, the patients were directed to have cold affusions to the nape of the neck and to the spine. The cold douche has been found to be a valuable adjunct to the treatment.

The constant current was employed in a few cases, but its application was not attended by any markedly good results. We think that its power to relieve choreic movements has been greatly overrated. In several cases there was a cessation of the movements while the current was passing.

In reviewing the table, we find that the result of treatment was—

Cures	16 cases.
Marked improvement	7 "
Result not known	4 "
Improvement	3 "
Total	30 "

It is highly probable that a number of the cases in which the notes "improvement," "result not known," and "marked improvement," were made, were ultimately cured, but neglected to return to make a final report.

A CASE OF SPINA BIFIDA CURED BY ASPIRATION AND INJECTION OF IODINE.

BY CHARLES M. ELLIS, M.D.

ON the 9th of May ult., I saw, in consultation with my friend Dr. R. C. Carter, a little girl, two years old, with a congenital tumor over the lumbosacral region of the spine. When first observed shortly after the child's birth, it was no larger than a hickory-nut, but had now attained a longitudinal diameter of three inches, the lateral diameter being rather less: it projected above the surface about one and a half inches. It was decidedly fluctuating, and pressure produced marked uneasiness and flushing of the face. In the erect posture the tumor was

tense and more resisting, but became soft and fluctuating when the child was laid on its face. It was a case of spina bifida.

The skin-covering was perfect, and the case was uncomplicated by hydrocephalus or other bodily deformity. The nutrition of the lower limbs was unimpaired. The child's health being in all respects excellent, I regarded it as a most favorable case for surgical interference. Using my hypodermic syringe as an aspirator, I evacuated the sac, drawing off more than six ounces of spinal fluid, and applied firm pressure over the sac by means of a double spica. This was done tentatively with the view of impeding its growth, which had recently been very rapid, until I could return at a future day prepared to attempt its radical cure. In a short time the sac refilled.

On the 3d of June I again saw the child. The tumor was a trifle larger than a month before. I again drew off the fluid by means of the hypodermic syringe, and, closing the orifice in the bony canal by my finger, I injected about three drachms of a solution of iodine and iodide of potassium: five grains of the former, and fifteen grains of the iodide, to an ounce of alcohol. Much to my annoyance, I was unable to aspirate the iodized fluid, and after a few minutes of unsuccessful efforts I threw into the sac a fluidounce of the spinal liquor, which had been kept at 100° Fahr. I now plugged the opening by a compress firmly held in place by a double spica. I have little faith, however, that I prevented the fluid entering the canal. For two or three days the child was very restless, had a high temperature,—106° Fahr.,—and frequent pulse, 140. No special symptoms of spinal irritation were developed. These unfavorable symptoms gradually subsided, and the child soon regained its accustomed health, and the tumor regained its former dimensions; but it was less elastic and less translucent, and gave to the touch a doughy feeling. The spica was replaced by an elastic pelvic bandage, which has since kept up constant pressure. Six weeks later, the tumor was notably smaller and harder, and at the date of this writing Dr. Carter informs me that the cure is perfect, the only remaining evidence of the tumor consisting in a thickening of the integuments.

With a properly constructed aspirator (Dieulafoy's), the retention of the iodized fluid would not have occurred, and the operation would have been at once executed with speed, safety, and success.

ELKTON, MD., November, 1873.

TINEA SYCOSIS.

BY JULIO J. LAMADRID, M.D.

AFTER reading the two interesting cases of tinea sycosis in a late issue of your journal, reported by Dr. George G. Wood, there recurred to my mind two similar cases which came under my observation during this year; and, as my treatment was different, and with as good success as that mentioned in Prof. Niemeyer's Practice and now recommended by Dr. Wood, I thought it a good

opportunity to have my two cases reported through the columns of your journal, for other physicians to give it a trial, as it is the easiest way to cure such cases.

Case I.—L. M., a mechanic, aged 35 years, of sound constitution, came to my office last May with an eruption of small acuminated pustules upon the chin and lower lip, which on close examination I found to be what is called the "barber's itch," contracted, five weeks previously to my seeing him, in a barber-shop. As there seemed to be a great deal of inflammation, I advised the application of poultices, and told him to call again in two days. I then had his beard removed with a pair of scissors,—not with the razor, as advised by Dr. Wood, for fear it would increase the irritation,—and prescribed for him the following:

R Acid. carb. cryst., gr. xxx;
Glycerinæ, f3i. M.

Sig.—To be applied twice a day, after the affected part has been thoroughly washed with tepid water and Castile soap. He called again in a week, completely cured, and remarked that in the future he would provide himself with a razor, etc.

Case II.—T. B., a clerk, aged 18 years, came to me last September, with the same complaint as Case I., with the exception of the disease being of less duration and severity, and accordingly I prescribed the acid in less quantity, and to be used as in the former case. In less than a week he was free from the disease.

BROOKLYN, L. I.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINICAL SERVICE OF PROF. DA COSTA.

Reported by R. S. KEELOR.

RHEUMATOID ARTHRITIS.

THE affection which we are about to consider has been known by various names, such as rheumatic gout, rheumatoid arthritis, etc., which latter has been generally adopted as a sort of compromise between the two prevailing and contending theories as to its nature,—rheumatic or gouty. It affects persons of an anæmic or scrofulous constitution, and is usually traceable to exposure to cold or damp. It begins with slight swelling of the smaller joints, as a rule, with tenderness, but no discoloration. The swelling is due to an inflammation, with effusion of water or pus, which finally subsides, and the swelling disappears. This is now followed by a thickening of the synovial membranes, and the formation of "vegetations," which gradually harden, and stiffness of the joint supervenes.

Second attacks are apt to follow upon partial convalescence, leading to complete disorganization of the joints affected; finally we find loss of articular cartilage, the bones, becoming eburnated, produce the peculiar grating sound noticed when the joints are moved. Dislocation is a frequent sequence.

The constitutional involvement is peculiar, and, as we become more familiar with the disease, affords a valuable aid in its diagnosis. It is usually subacute, and presents no fever-phenomena, no uric acid or increase of fibrin in the blood, and no acid perspiration; neither are there deposits in the finger-joints and ears, as in gout. There is no history of hereditary rheumatism or gout. The absence of cardiac symptoms is peculiar. These lesions are so intimately associated with rheumatism as to warrant the assertion that four-fifths of the cardiac diseases are attributable to

rheumatism. These points in the diagnosis and clinical history are proofs of its being a *distinct disease*.

Appended is the clinical history of two cases in point:

Case I.—A man, aged 30 years, a shoemaker by trade, first became affected, two years since, with swelling, pain, and stiffness in the great toe of the left foot, which have extended to all of the larger joints. He gave, upon admission, a history of previous good health; never had fever during the progress of his disease; never had syphilis; and there is no family history of gout or rheumatism. It came on gradually. His urine is normal, bowels regular, and he has a good appetite. He has lost flesh, but is now gaining again. The hands present the peculiar distorted appearance of the disease, and there is "grating" upon motion; the large joints are alike affected, being rigid and painful upon motion. Auscultation reveals, at the base of the heart, a soft systolic murmur, which is not constant; there is no hypertrophy. He has been taking citrate of lithia and cod-liver oil; this, conjoined with baths and regulated diet, has produced favorable results.

Case II.—A French sailor, who has been in the house five days, states that he has been affected two months, giving no acute history; there is some stiffness of the smaller joints, entire absence of heart-lesions, no fever, tongue somewhat coated, pulse and temperature normal.

This patient might take, with advantage, lithia, cod-liver oil, or arsenic, internally, while he is kept at rest in bed, and leeches applied, then cold water or lead-water and laudanum applied locally. Frequently diuretics and occasional purging are useful in the early stages of the disease. If there is much weakness, quinia is given with advantage.

Later in the disease the local indications require more urgent treatment, and here iodine may be used freely, or, better, the following:

R Potass. iodid., ʒij;
Lin. sapon. camph., fʒvj;
Tr. belladonnæ, fʒij;

to be applied morning and evening.

Ammoniacal and mercurial plaster may serve a good purpose.

Internally, cod-liver oil, potass. iodid., liq. potass. arsenit., iodide of iron, and citrate of lithia, are the remedies *par excellence*. A formula now used in the hospital is—

R Effervescing citrate of lithia, gr. iij to v;
Cod-liver oil, fʒss.

Arsenic is valuable; in fact, no case should be pronounced incurable until it has been tried. If the nutrition fails, the system may be supported with stimulants, as there is no contra-indication, as in gout or rheumatism: they are not to be used in the acute form of the disease, however.

Baths should be insisted upon; for this purpose tepid water and carbonate of soda may be employed, or Turkish baths may be used. Finally, a change of climate may be of service.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. H. C. WOOD.

CASE OF BRIGHT'S DISEASE, WITH LEUCOCYTHÆMIA AND DISEASE OF THE BONE-MARROW.

MICHAEL F., aged 26, native of Ireland, laborer, admitted to the hospital October 5, 1873. Family healthy, to the best of his knowledge. In May, 1865, while in Baton Rouge, Louisiana, was attacked with vomiting, which occurred every day; for this he underwent treatment, but does not recollect how long this sickness lasted. No pain or other symptoms than

vomiting. Nearly two years after this, while in Indiana, he was similarly attacked; the vomiting being accompanied with cold sweats. This spell of illness lasted three or four weeks. About a year after this, he was again similarly affected. These attacks have occurred ever since, at intervals, up to the time of admission, Oct. 5.

About three days before admission he was seized with pain in left side and back, accompanied with cold sweats. About five days after admission, commenced bleeding at the nose (profusely), which has recurred three or four times, but was eventually stopped by the use of Monsell's solution.

October 22.—Four days ago the patient commenced bleeding at the gums, which still continues. There has been no vomiting since admission.

Microscopic examination of blood showed a moderate increase of the white blood-corpuscles. The urine is distinctly albuminous.

No decided enlargement of the spleen can be made out, but the axillary and inguinal glands can be felt to be somewhat hypertrophied. The general anæmia is profound.

October 28.—Bleeding from the mouth has continued, at intervals, since the last note, up to his death, which occurred last night, from exhaustion. The oozing of blood seemed to be general from all parts of the mouth.

Autopsy.—Spleen slightly enlarged; no lymphoid points visible in it; weight 9½ ounces. Pancreas abnormally hard; weight 4½ ounces. Glands of axillæ and inguinal region somewhat hypertrophied, but scarcely larger than filberts; lymphatic structure elsewhere apparently not affected. Kidneys very small, offering on microscopical examination the usual lesions of "contracted kidney."

The tibia, when sawn open, offering apparently healthy marrow, approximating lemon-yellow, and normal in appearance. The marrow of the femora dark red, presenting the general appearances seen in cases of leucocythæmia elsewhere reported by Dr. H. C. Wood. The sawn femora were handed to Dr. R. M. Bertolet, Microscopist to the Philadelphia Hospital, for examination. He reports as follows:

"DEAR DOCTOR,—The marrow of the long bones, from the case of leukæmia, after having been exposed to the air for some time, presented an unusually soft, almost fluid mass, of a grayish-red color, closely resembling in both color and consistence muco-purulent matter which has been tinged with blood.

"The microscope showed an enormous increase of the so-called lymphoid elements, which have been described by Neumann as intermediate forms between the white and red blood-corpuscles. These lymphoid elements are quite small in size. Large cells with a distinct cell-wall were also seen, containing from eight to twenty blood-corpuscles. The fully-formed red disks, although quite numerous, were less abundant than the intermediate lymphoid forms."

BELLEVUE HOSPITAL, NEW YORK.

BY W. H. FARRINGTON, M.D.

DISLOCATION OF THE SIXTH CERVICAL VERTEBRA.

R. C., æt. 45; West Ireland; domestic; admitted November 17. Family history good. Patient drinks liquor occasionally, but never to excess. About six months ago had facial erysipelas, but with this exception her health has always been excellent. About four P.M. the day preceding her admission, patient went to visit a friend residing in the lower section of the city. The husband of the latter kicked her off the stoop, quite a high one,—then knocked her into the gutter, and bent her head over on the chest so that it touched

the pavement between her limbs, kicking her also several times in the back and on the neck. She remained in this condition several moments, and was then carried to a police-station, where she remained over night, entering the hospital this morning. After the reception of her injuries she was perfectly conscious, and could speak without difficulty, but on attempting to move found herself unable to do so. On admission, patient is a stout well-nourished woman. There is no paralysis of the face or deflection of the tongue; the mind is perfectly clear; no difficulty of speech; pupils are rather contracted. There is general paralysis of the arms, legs, and body, with the following exceptions: She is able to flex both forearms, the left one the most readily. Sensation is retained on the outer side of both forearms, but not in the hand. Sensation is unimpaired also on both sides of the chest as low down as the nipples. She is unable to extend the forearm or to move the fingers. Reflex action is very slight, the great toe alone moving when the foot is pricked. Respiration is almost entirely diaphragmatic. Complaints of pain in the back and in the neck, but no bruises are found, nor is deformity or crepitus evident. No point of tenderness found except in the lower portion of the neck on the right side behind. The extremities are flaccid. She has passed no urine or fæces since her injury. Has constant thirst, but no sense of hunger. No difficulty in swallowing. Abdomen tympanitic. Has numbness in the hands and feet, and in the legs above the feet, but how far this extends she is unable to say. Breathes without difficulty. Physical examination of lungs is negative. Hepatic and splenic dullness masked by tympanitis, but the spleen appears somewhat enlarged. The apex-beat of the heart is about an inch below and the same distance outside the nipple. No œdema of legs. Urine 1021, acid, negative. Pulse 80; respiration 28; temperature $101\frac{3}{4}^{\circ}$.

Patient was seen to-day by Professors Wood, Janeway, Sands, and Mott, all of whom deemed it advisable not to disturb her.

Dr. Sands related a case similar to this, in which the patient died in being transferred to another ward. The diagnosis made was dislocation of the fifth and sixth cervical vertebræ. P.M.—Pulse 72; respiration 24; temperature $100\frac{1}{2}^{\circ}$.

November 20, A.M.—Pulse 84; respiration 22; temperature $101\frac{1}{4}^{\circ}$. Patient is perfectly conscious and rational; talks well. Has little or no appetite, but has constant thirst. Paralysis remains about the same. Has had no movement of the bowels since admission. Urine still has to be drawn.

November 21, A.M.—Pulse 84; respiration 20; temperature $100\frac{1}{2}^{\circ}$. P.M.—Pulse 90; respiration 28; temperature $101\frac{3}{4}^{\circ}$.

Patient has been in about the same condition all day. Is perfectly conscious still; vomits a great deal; bowels have not yet moved.

November 22.—Condition unchanged.

November 23, 8.30 A.M.—Temperature 108° ; stertorous respiration; inability to speak; contraction of the pupils. Patient is rapidly sinking. Paralysis as before. Vomits up a dark coffee-ground material.

12 noon.—Temperature 107; has had a few light-colored loose stools.

1.45 P.M.—Patient died.

Autopsy by Dr. Janeway.

Exterior.—A well-nourished woman. No ecchymoses on the body. On making an incision through the skin to open the spinal column, a clot of blood is found in the dorsal region on the fascia covering the erector spinæ muscles, and also around the lower cervical vertebræ.

Vertebral Column.—The sixth cervical vertebra is dislocated forward on the seventh; the intervertebral

cartilage is ruptured, and the anterior common ligament somewhat torn; the ligamenta subflava torn on both sides, and the articular processes separated so that those of the sixth are carried in front of the seventh. Very little clotted blood on the dura mater, which is not torn.

Lungs.—Marked hypostatic congestion.

Heart.—Slight calcification at the base of one leaf of the aortic valves. Other organs are normal.

ANEURISM OF THE THORACIC AORTA RUPTURING INTO THE SUPERIOR VENA CAVA.

C. D., æt. 61; West Ireland; domestic; admitted September 18, 1873. Father died of old age, and a brother of heart-disease. Patient has been in the habit of moderate indulgence in ale and gin. No history of venereal. Had an attack of acute articular rheumatism seventeen years ago, but with this exception her health has always been good.

About one year ago, patient noticed a small tumor in the right side of the chest, near the sternum, whose development appears to have taken place without pain. She has been required by her occupation to make straining efforts in lifting heavy baskets of clothes, but knows of no further cause. About two months after its first appearance she experienced sharp pain running down the inner side of the arm to the elbow, and occasionally acute pain in the chest in the region of the tumor, but has not had any dyspnoea. These pains have persisted up to the present time. Her voice has been hoarse for several months past, but she has not had cough for the last eighteen months.

On admission, patient is an exceedingly nervous woman, of moderate nourishment. Complains principally of a tumor in the chest. Has no pain here at present. Appetite good, bowels regular, and tongue natural. Pulse natural in frequency, short and sharp in stroke, with no evident difference in the radial pulsation on either side. No difference in size of pupils. Respiration accomplished without difficulty. No cough. Voice rather hoarse, but no other symptom of laryngeal disturbance. Chest-examination reveals the presence of a pulsating tumor on the right side of the sternum, extending from the second rib downward as far as the fourth, and about three inches outwards from the right border of the sternum. Dullness on percussion exists, and a marked heaving impulse and thrill on palpation. A double murmur is heard with greatest intensity over the tumor, transmitted into the vessels of the neck. Of these the diastolic is heard most distinctly; apex-beat of heart in the fifth interspace on the mammary line; a systolic murmur heard at the apex. Lungs appear to be normal. Ordered rest in bed, and potass. iodid., gr. x, three times daily.

November 15.—General condition unchanged. Physical examination reveals some increase in size in the tumor. Complains only of slight occasional pain in the chest.

December 2.—Up to the present, patient does not appear to have suffered from dyspnoea. At 2 P.M. she was carried on a stretcher to a clinic in the hospital amphitheatre. She was, as usual, highly excited. While returning to the ward she was noticed to be deeply cyanosed, and to suffer great dyspnoea. Extremities cold, pulse small and rapid. 5 P.M.—Patient feels somewhat better, but her dyspnoea and cyanosis persist, as well as the coldness of the extremities, but in a less degree. 10 P.M.—Patient has had an attack of nausea and vomiting. Symptoms much worse than before. Pulse feeble and accelerated. She is exceedingly restless. To quiet this, sol. morph. Magend., $\mathfrak{M}\mathfrak{v}$ vi, are administered hypodermically, with temporary relief.

December 3, 5.30 A.M.—Patient continued in about

the same condition during the night, and at this hour died.

Autopsy by Dr. Janeway.

Brain and membranes normal.

Thorax.—An aneurismal sac of the size of an apple arises from the aorta at the junction of the ascending and transverse portions. It projects forwards and to the right; has eroded the second costal cartilage and destroyed the intercostal muscle of the second interspace. The aneurism compressed the vena cava descendens; and at the point of junction of the right and left innominate veins on the inner wall of the vena cava a transverse slit is found, one-half inch in length, serving as a communication between the aneurism and the vein. The former is attached to the upper lobe of the right lung.

The aorta is diseased throughout its course by chronic endo-arteritis. In the descending aorta a true aneurismal sac exists, pressing against the upper lobe of the left lung, to whose pleura it is adherent.

Heart.—Aortic valve thickened and slightly insufficient. Calcareous plate at the base of the mitral; no hypertrophy; walls normal.

Spleen normal.

Kidneys rather smaller than usual, with commencing granular degeneration.

TRANSLATIONS.

IMPORTANCE OF GELATIN IN NUTRITION.

VOIT, Bischoff, and Fr. Hofman ascertained, by a series of experiments on dogs, that the addition of gelatin to the food always reduces the consumption of albumen. This effect is observed when large as well as when small quantities of meat are fed at the same time with the gelatin. Particularly when meat is given sparingly, gelatin serves to economize albumen to a much greater degree than fats and carbohydrates. The amount of albumen which is thus saved is in proportion to the amount of gelatin given. Still, an appreciable quantity of albumen is constantly consumed, even when a large excess of fat is added. Fat and gelatin together decrease the consumption of albumen more than gelatin alone.

Gelatin is quickly decomposed after being absorbed in the alimentary tract. The experiments demonstrated that a deposit of gelatin in any one of the organs is not possible. Gelatin can therefore substitute only a portion of the requisite albumen, and not all of it. Gelatin cannot even take the place of the tissues producing it, since these originate from albuminous substances.

Voit has explained at some length his conception of the differences between the two varieties of albumen found in the human body, which he distinguishes as organic and circulating albumen. The former is a constituent of the tissues, and is decomposed with difficulty, while the latter occurs in the circulating fluids and is readily converted. The fact that neither gelatin, nor fats and carbo-hydrates, are able to prevent the conversion of albumen completely, is most readily explained by their inability to replace organic albumen and to form organs and tissues. No new blood-corpuscles to take the place of those which have been destroyed, no new muscular fibre, nor even a tissue producing gelatin, can be formed from gelatin itself. But when gelatin alone is given, a smaller amount of the organic albumen is transformed into circulating, or albuminose, so that the organism loses less albumen than it would otherwise do.

When gelatin is administered in conjunction with a little albumen, the consumption of organic albumen is very much reduced. Gelatin with an excess of albumen increases the amount of organic albumen in the tissues. Gelatin is subject to conversion, in a manner similar to albuminose, and saves albumen on account of being more readily decomposed than organic albumen.

As gelatin cannot substitute organic albumen, but only limits the conversion of the latter into albuminose, in place of which it is itself decomposed, an animal cannot be supported on it for any length of time, from want of albumen, even when fats, carbo-hydrates, and salts are given in sufficient amounts. Gelatin is, consequently, not properly a nutrient; but still it serves the purposes of nutrition in an indirect manner. It differs from other alimentary bodies in not being able to substitute any one of these completely, while fat and carbohydrates can entirely prevent the waste of fat, and while each inorganic constituent has the property of substituting itself.

Gelatin is not a plastic aliment in the old acceptance of the term, as it takes no part in the elaboration of the tissues. Even as a respiratory element it is of very slight importance, no more, in fact, than was formerly accredited to albumen. But on account of the facility with which it is decomposed in the body, it serves a useful purpose in economizing both albuminose and albumen. Its action in this respect is similar to that of fats and carbo-hydrates, but its effects are much more marked. In addition, gelatin was found to prevent the destruction of a small amount of fat. *Zeitschrift für Biologie*, 8th vol., 3d no.—*Chem. Techn. Mittheilungen von Elsner. Industrieblätter von Hager u. Jacobsen*.

PREPARATION OF KOUMYS.

H. & N. SCHULTZE, of Berlin, give the following formula. Unskimmed cows' milk is mixed with a sufficient amount of sugar of milk to produce in the course of the subsequent fermentation in closed vessels, a carbonic acid gas pressure of four atmospheres. Fermentation is induced by the addition of brewer's yeast, which has been thoroughly washed. The operation is commenced in open tanks, in which the mixture must be frequently stirred. One-half of the casein, which is separated, is to be skimmed off. While the fermentation is actively progressing, the preparation is drawn off into champagne-bottles, the corks of which must be securely tied down by string or wire. They must then be removed to a cool locality, so that the fermentation can be properly completed. Three varieties of koumys are prepared, which differ in the amount of carbonic acid gas with which they are impregnated; they result from varying the proportion of sugar of milk, which is originally added.

C. Schwalbe makes koumys from condensed milk in the following manner. 100 c.c. are dissolved in a small amount of cold water; 1 gramme of lactic acid and $\frac{1}{2}$ gramme of rum are added, and the mixture is diluted with sufficient water to make it measure 1000 to 2500 c.c. This preparation is put into a Liebig's bottle and charged with carbonic acid gas. The bottle is to be kept in a warm room, and to be examined after three or four days. When there is an active evolution of froth, and when the curd is of a fine, granular consistence, the koumys is in the proper condition. It can then be kept for about eight days.—*Deutsche Industriezeitung*, p. 438, *Chemisches Centralblatt*, p. 568.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 3, 1874.

EDITORIAL.

THE ZERO OF WORTHLESSNESS AND THE ACME OF EXCELLENCE.

IT is said that misery makes strange bedfellows ; but no stranger contact can be seen than occurs in some of the crowds after an exciting and critical election, when the millionaire hustles, or is hustled by, the pauper or the rag-picker, whose bosom swells for once with pride, because he has just exercised the inalienable right of an American,—the right of suffrage,—whose being is to itself glorified by the thought that its printed decision bears as much of power as does that of the mightiest intellect or of the profoundest statesman in the land. Often does the book-shelf remind us of an election crowd ; and to-day Dives and Lazarus, wisdom and ignorance, honor and disgrace, it seems to us, are represented by two books which now jostle each other on the table before us. Of course it is not necessary to tell any of our readers what book we refer to as Lazarus. We opine that if in any intelligent medical circle of the land allusion should be made to an unnamed book as the national disgrace, nine out of ten of those present would know it was the Transactions of the American Medical Association which was referred to. Yet, like Paul, let us take courage ; let us praise the noble band of censors, the publication committee : the book is some three hundred pages shorter than its next elder brother. Let us trust that next year a publication committee may be found possessed of suffi-

cient “back-bone” to declare that nothing that is not of real scientific interest shall go into the volume, and that power be granted them to carry out the determination. What a saving of funds would there be ! What a loss to friend Collins, the printer ! Surely the title-page would be the sole solace left to him.

Dives is a book* well known to our readers, and of which every American ought to be proud. When the learned author of the work passed away, probably all of us feared lest the book should not maintain its place in the advancing science whose terms it defines. Fortunately, Dr. Richard J. Dunglison, having assisted his father in the revision of several editions of the work, and having been, therefore, trained in the methods and imbued with the spirit of the book, has been able to edit it, not in the patch-work manner so dear to the heart of book-editors, so repulsive to the taste of intelligent book-readers, but to edit it as a work of the kind should be edited,—to carry it on steadily, without jar or interruption, along the grooves of thought it has travelled during its lifetime. To show the magnitude of the task which Dr. Dunglison has assumed and carried through, it is only necessary to state that more than six thousand new subjects have been added in the present edition. Without occupying more space with the theme, we congratulate the editor on the successful completion of his labors, and hope he may reap the well-earned reward of profit and honor.

IT affords us much pleasure to state that Dr. Barnes, Surgeon-General U.S.A., was recently elected, by a vote of forty-two out of forty-six, a corresponding member of the Academy of Medicine of France. We are sure that this announcement will be highly gratifying to every American physician and surgeon. Considering the great services which Dr. Barnes has rendered to his country by the creation of the most magnificent military museum in the world, and the publication of the Medical and Surgical Memoirs of the Late War, the most copious and complete ever issued by any people, such a compliment was well deserved, and reflects great credit alike upon France and the United States. We are informed that the announcement of the election of the Surgeon-General came, very appropriately, from Baron Larrey, who accompanied it with some highly complimentary expressions.

* A Dictionary of Medical Science. By Robley Dunglison, M.D. A new edition, by Richard J. Dunglison, M.D. Henry C. Lea, Philadelphia, 1874.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES.

IN the report of a case of malignant disease of the ear, with paralysis of some cranial nerves, in one of your late numbers, a considerable degree of hypertrophy of the corresponding side of the tongue was recorded among the symptoms. It was found so difficult to offer a rational explanation for this, that the possibility of a congenital malformation of the tongue was suggested.

In Dr. C. W. Burnett's very interesting and valuable report on the progress of otology, just published, I find an observation on the physiology of the chorda tympani which I had not met with before, and which throws some light on this singular phenomenon. Some experiments performed by Vulpian show that "the fibres of the chorda tympani which accompany the lingual nerve in its distribution to the tongue have the same influence on the vessels of that organ, *i.e.*, direct dilating influence, which the fibres of the chorda tympani possess over the submaxillary gland, as already proved by Cl. Bernard."

If we suppose that a more or less prolonged irritation of the chorda tympani preceded its final paralysis, this dilating effect upon the vessels affords an explanation of the hypertrophy of that part of the tongue to which the fibres of this nerve are distributed.

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

NOVEMBER 3, 1873.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

PRESENT—Messrs. Tyson, I. Norris, J. G. Hunt, Wells, Schaeffer, Buckingham, McQuillen, Allen, and Richardson.

Dr. JAMES TYSON exhibited some beautiful specimens of echinococci removed from a cyst the size of a hen's egg in the liver of a patient who died recently in one of his wards of the Philadelphia Hospital. Dr. TYSON remarked this was the first case of perfect echinococci from an hydatid cyst that he had ever seen. The *Tænia echinococci*, a small, short tape-worm composed of four joints (which develop from these echinococci), only reaches its full growth and acquires reproductive powers in the bodies of the dog and wolf. The larval cysts are each furnished, as the specimen showed, with thirty-four hooklets arranged in a circle around the mouth, and each attached originally by a sort of fleshy stem or peduncle to the membrane, forming the inner layer of the parent cyst-wall, which to the naked eye appears covered with minute granules, every one of which is found to be an echinococcus.

Dr. J. GIBBONS HUNT showed for comparison an hydatid cyst with fully-developed larvæ, from the body of a rabbit.

In reply to a question, Dr. TYSON observed that among the specimens upon the table, one in which the larvæ were mounted in glycerin showed the character-

istics in the most satisfactory state of preservation, while those put up in creasote-water soon become putrid.

Dr. HUNT inquired if any positive explanation could be given as to the way they found entrance into the liver.

Dr. TYSON replied that they probably bored their way into that organ after perforating the stomach, into which they enter with other ingesta, as is known to be the case with the *trichina spiralis*.

Dr. J. G. RICHARDSON suggested that, since these parasites were so common in the liver and rare in the spleen and pancreas (which also adjoined the stomach), perhaps ova of the *tænia* after being swallowed were taken up by the blood-vessels of the intestinal villi, and, being conveyed by the portal vein to the liver, and there filtered out as it were, thus owed their position to the blood-current in the portal circulation.

Dr. J. G. HUNT observed that he had found the best way to display the hooklets was to decapitate the echinococcus and then illuminate the head by the aid of polarized light.

Dr. J. H. MCQUILLEN exhibited a left superior central incisor tooth, the crown of which was bent at right angles with the root, and remarked that the specimen had been sent to him by J. M. Comegys, M.D., of St. Albans, Vermont, with the following history: The patient from whom the tooth was removed, when a child four years of age, fell and knocked out the left superior deciduous incisor, sustaining at the same time some injury to the surrounding parts. Several years passed over, and all the permanent teeth, with the exception of the left superior central incisor, made their appearance in due time, but, being very defective in structure, they were removed and an artificial denture inserted. After wearing these a short period, the patient noticed a fungous growth of the gum near the centre of the upper jaw, and on incising this a hard substance was found, which was pronounced to be a portion of the alveolar process. Suffering continued annoyance from this protuberance, the patient called upon another operator, who (also regarding it as a piece of the alveolar process) made an unsuccessful attempt to remove it; and, at last, the patient eventually coming under the care of Dr. Comegys, he extracted it. The specimen is unique, and illustrates a condition denominated by Mr. John Tomes "Dilaceration." The history of this case manifestly affords strong support to the position assumed by Mr. Tomes,—to wit, that the peculiar relation which the crown bears to the root is due to the fact that, by mechanical violence at a period when the crown of the permanent incisor was partly calcified, its position in the jaw was changed so that it was turned outwards or inwards, there to remain in a state of rest, whilst, the pulp being uninjured, the development of the tooth continued after the accident, with a permanent displacement of the crown. Prof. Wedl, of Vienna, objects to the term "dilaceration," suggesting in place of it flexion or torsion of the crown, and states that in cases which came under his notice the patients did not remember having sustained any injury of the jaw by falls or blows. Such accidents, however, may have occurred, and afterwards escaped their recollection.

Dr. MCQUILLEN cited a case which had come under his own immediate notice, in which a child four years of age, playing about a room, fell and struck her right superior maxilla with considerable force against the edge of a table, cutting through the outer plate of the alveolus. Sixteen years have elapsed since the accident, and the right superior canine tooth has failed to make its appearance. A very decided protuberance exists, however, on the inner margin of the alveolar process, opposite the vacant place of the tooth, which he has reason to believe is due to the presence of the

crown of the unerupted canine, whose position it is reasonable to infer was forcibly changed at the time of the accident.

A large plaster model, used for class demonstration to illustrate dilaceration of the crown of an incisor, was exhibited, and he then placed under one of the microscopes a longitudinal section of a dilacerated incisor, prepared by Dr. George S. Allan, of New York.

In this specimen the dentinal tubuli at the neck of the tooth, where the bending occurred, presented a marked crimped or crenated appearance.

Dr. McQUILLEN also exhibited two valuable and interesting specimens received from Dr. R. R. Andrews, of Cambridge, Massachusetts; one of them displaying blood-vessels in the dentine of a molar tooth; the other being a human embryo of the age of twenty-nine days.

Dr. HARRISON ALLEN narrated the post-mortem appearances of a malformation of the kidney, occurring in a case which he had recently observed. The peculiarity consisted in an elongation of the organ, and its being furnished with two ureters, which took their origin from the upper and lower portion of the hilum at a distance of about one inch apart, and, gradually converging, entered the bladder within about one-eighth of an inch of each other.

Dr. ALLEN remarked that this abnormality was entirely ignored by several high authorities, Henle alone mentioning it, and although he states it is not so rare as to be anything of a curiosity, yet it would seem to be at least quite unusual.

Dr. J. G. HUNT exhibited three specimens of the larvæ of *Anthomia* (a species of fly), which had been passed from the human intestine, and whose appearance might have caused considerable anxiety if they had remained unrecognized.

He also displayed an entire leaf of *Limnanthimum lacunosum* (one of the *Gentianaceæ*), showing curious radiating cells somewhat resembling the bone-corpuscles, but very much larger, and quite unlike those of any other vegetable tissue. During the existence of the plant these cells ordinarily contain bubbles of air, and perform the part of minute life-preservers by supporting the leaves upon the surface of the water.

REVIEWS AND BOOK NOTICES.

A PRACTICAL TREATISE ON THE DISEASES OF THE EAR, INCLUDING THE ANATOMY OF THE ORGAN. By D. B. ST. JOHN ROOSA, M.A., M.D. Illustrated by Wood Engravings and Chromo-Lithographs. New York, William Wood & Co., 1873.

"This work is intended to be a guide to those who wish to treat diseases of the ear."

These are the words which open the preface to this very valuable work; and, after a careful examination, we believe the intention of the author has been ably carried out. The work contains five hundred and thirty-five pages, and is divided into four parts, which treat respectively of the external ear, the middle ear, the internal ear, and deaf-mutism and hearing-trumpets. There is also a very interesting and accurate history of the progress of otology from the year 460 B.C. to the present time, which precedes the description of the anatomy of the auricle and external auditory meatus.

The directions for examining aural patients are very explicit, and the chromo-lithographs illustrative of the appearance of the membrana tympani are exceptionally good. The perspective of the lithographs in this work is strikingly brought out by viewing them through any short tube, but preferably with the ordinary aural speculum.

Otitis parasitica, a disease which appears to be more common than heretofore supposed, is thoroughly explained by accurate wood-cuts and a fully-condensed experience of authors on this topic.

The chapter on Injuries of the *Membrana Tympani* shows that, although many injuries to this part of the ear arise from unavoidable causes, unskilled manipulation on the part of the laity, in their anxiety to relieve the patient, may perforate or destroy this delicate membrane, which might have been saved had the surgeon been called upon for relief. The chapters of this work which contain the author's experience and views upon chronic non-suppurative inflammation of the middle ear are the prominent feature of this treatise. The author divides the so-called chronic catarrh of the middle ear, or chronic non-suppurative inflammation of the middle ear, into—1, *chronic catarrhal inflammation*, and, 2, *proliferous inflammation*. The latter term is original with the author, or rather it is, as Dr. Roosa says, an original translation of the German word *Wucherung*.

This endeavor of the author to differentiate the forms of chronic disease of the middle ear is in perfect harmony with similar endeavors of Politzer, Gruber, Weber-Liel, and others; the first-named of whom divides chronic catarrhal diseases of the middle ear into secretory and non-secretory forms; the second authority has described an otitis media hypertrophica; and the last-named writer has recently published his well-known work "On the Nature and Remediability of the Most Common Form of Progressive Hardness of Hearing," which malady, he says, cannot be referred to catarrhal causes, but even as a primary disease must be considered as a disease of the structures of the middle ear dependent upon "affections of the nerves which supply, and which stand in close relation to, the middle ear." In this attempt on all sides to describe a separate chronic disease of the middle ear, based upon a special group of pathological alterations of the component parts of the tympanum, we recognize the fact that there is a frequent form of deafness which cannot be referred to catarrhal causes at all. Therefore Dr. Roosa endeavors to describe "a form of inflammation which shows a higher formation than the catarrhal," and, while admitting that catarrhal symptoms may precede this form of disease, he shows that there is a disease of the ear which tends towards a chronic progress, and which he has "ventured to designate the *proliferous form*."

These views of the author are based upon twelve varieties of tissue-changes which have been frequently found as a consequence of this form of ear-disease, and in them we find that the prominent feature of the pathological processes is the formation of new tissue; and it is this fact that has induced and really warrants the application of the word "proliferous" to this form of ear-disease.

In the chapter on the Treatment of Chronic Non-suppurative Inflammation of the Middle Ear, Dr. Roosa says, "In one respect the treatment of the catarrhal may be fairly distinguished from that of the proliferous form. In the catarrhal form we must give a great deal of attention to the naso-pharyngeal space, while in the other we need to pay very little to it." With this exception, the outline of treatment for both forms of the disease may be the following: constitutional and hygienic, local blood-letting, applications to the Eustachian tube, applications to the cavity of the tympanum, and cutting operations upon the membrana tympani and the ossicula.

Under the head of the nasal douche the author expresses his views against its use, since he has found it to be "sometimes a troublesome and dangerous appliance."

This surely will be the case if the instrument is im-

properly used; but if the fluid injected into the nares be warm, if the vessel containing the fluid be not higher than the patient's forehead, and if after using the douche the patient do not leave his room for at least fifteen minutes, we have yet to hear of any accident such as Dr. Roosa depicts.

It is not stated, in the table which is given by the author to show the danger of the application of the nasal douche, whether *all* these rules were observed; and, although it is implied that they were, still it is not clearly shown, for the instructor in the use of the douche in thirteen cases of the sixteen unfortunate ones is either unnamed or "unknown," and in several cases the nature and temperature of the fluid injected are also "unknown," except in one case,—that of Dr. Frank,—in which it is distinctly admitted that the injected fluid was cold; and, as we are prepared to hear, the result was an acute otitis media.

We cannot admit, as Dr. Roosa does, the statement that "the instructor in the use of the douche was a physician" as a sufficient guarantee of the correctness of the instruction," for our experience shows that as a rule the patients have failed to receive *all* of the aforesaid precautions. And even if the physicians who instruct the patients in the use of the douche give proper instruction, the patients themselves may fail to follow their directions. It is obvious where the blame rests in such cases.

Operations upon and through the membrana tympani, which now form some of the most important operations in surgery, are illustrated by history, cases, and woodcuts of the various instruments employed, from "Cheselden's experiments on dogs to Weber-Liel's operation upon the tensor tympani muscle."

At the end of the fourteenth chapter we find a table showing the results of treatment of chronic non-suppurative inflammation of the middle ear, based on the observations of four observers, of whom Professor Roosa is one. In commenting on this table, Professor Roosa says, "I can only account for the fact that my percentage of cures is less than the others from the supposition that I have seen a proportionately larger number of neglected cases than falls to the lot of other practitioners."

We note, however, that the percentage of *improvement* in our author's cases is greater than that of the others. Dr. Roosa also states that he has made the standard of cure very high, and has not called a case "cured" which has only been greatly improved.

The chapter on Acute Suppuration of the Middle Ear serves to mark an era in the treatment of disease in general. Our author, firmly supported by the experience of modern otology, shows that the treatment of this form of ear-disease is not only rational and successful, but is demanded, by the exigencies of the case and the evils of neglect, from every intelligent and conscientious physician. If any one should doubt the desirability of treatment in acute otitis media, he has but to peruse the chapter on Chronic Suppuration of the Middle Ear and its fatal consequences, in order to have a good reason for changing his opinion.

"The general health of a patient affected with chronic suppuration of the middle ear is usually impaired, even if none of the serious consequences have occurred. Such a drain is not tolerated with equanimity by nature."

"Dr. Hackley has found albuminuria in a number of cases of chronic suppuration of the middle ear, where there was no apparent cause for the disease except the long-continued secretion of pus from the tympanic cavity."

One hundred pages are devoted to a consideration of the consequences of chronic purulent discharges from the tympanum, and the treatment in these very grave cases.

To this portion of the treatise Dr. Roosa has appended a table, "compiled from various sources, which illustrates in a striking manner the fatal consequences of some cases of aural disease."

The portion of the work which treats of the middle ear and its diseases closes with these words, in reference especially to the table of cases already alluded to: "Taken in connection with the fact already stated, that suppuration of the ear is more frequently the cause of cerebral abscess than any other one disease, these cases form a complete justification, if one were needed, for the giving up so much space to the consequences of chronic suppuration of the middle ear. If the table should startle some mind hitherto inattentive to this subject into a realization of its grave importance, and lead to a more careful consideration of an ulcerated middle ear, it will have accomplished its object." The remaining pages of the book are devoted to the anatomy and diseases of the internal ear, and to deaf-mutism and hearing-trumpets.

True nervous deafness, "a primary affection of the auditory nerve or labyrinth, or of both," is said to be a rare disease. In fifteen hundred cases of aural disease observed by the author, only fifty-seven could be fairly considered as primary diseases of the internal ear.

In alluding to hearing-trumpets, the conclusions are that the simpler tubular apparatus are the best, but the small "invisible tubes placed in the auditory canal are wholly useless." We close this notice with a hearty recommendation to all interested in diseases of the ear to peruse this work.

C. H. B.

GLEANINGS FROM OUR EXCHANGES.

THE ELASTIC LIGATURE (*British Medical Journal*, November 29, 1873).—On the 21st instant, Sir Henry Thompson demonstrated, for the first time in England, a surgical procedure which has been practised for some time past by Professor Dittel, of Vienna. It consists in substituting an innocent-looking elastic thread for the formidable array of knives, tourniquets, artery-forceps, and other paraphernalia with which the surgeon ordinarily approaches the patient. Before proceeding to perform the operation, Sir Henry related the curious accident by which Professor Dittel was first led to appreciate the extraordinary results which may be produced by the slight yet continuous pressure of a simple elastic thread. He was called to see a girl about eleven years of age, who was suffering from acute and severe but somewhat anomalous brain-symptoms. The case was altogether obscure; the girl seemed in other respects healthy, but could give no account of herself,—she was, in fact, at the point of death,—nor could any satisfactory history be obtained from her friends. The attack soon proved fatal, and Professor Dittel made a necropsy. It was then found that the india-rubber band of the hair-net which she was wearing had ulcerated through the whole thickness of the calvarium, and had set up meningitis. On further inquiry, it was ascertained that the girl, having been constantly scolded by her stepmother on account of the untidy state of her hair, had, about three weeks before her illness, purchased an ordinary hair-net, and the elastic thread of this net, tied round the head and worn day and night, had, in less than a month, cut through skin and bone and penetrated to the brain, and this apparently without causing any pain to the patient.

Professor Dittel at once proceeded to reduce to practice the ideas suggested to him by this unfortunate accident. He first applied it to a case of nævus of the scalp in a child; then, finding that the plan quite answered his expectations, he applied it to the removal of the tes-

ticle, penis, etc., and finally to the amputation of limbs. He has now performed, by means of the elastic ligature, a large number of operations of all kinds, including five amputations of limbs. It is not understood, however, that he proposes to apply his method to the performance of the larger amputations: these were done rather with the view of testing the capabilities of the process. The time required for the completion of an operation varies according to the amount and density of the tissues which have to be divided: *e.g.*, for the separation of the mamma from eight to twelve days are required.

The chief advantage which Dr. Dittel asserts this plan to possess is, that patients so operated on are less liable to pyæmia than those treated in the ordinary way. He bases this assertion on the experience of the numerous cases referred to above. Remembering also what a morbid dread of the knife many nervous patients have, the depressing mental effects of an operation may often be greatly diminished. Lastly, the operation itself is absolutely bloodless.

Among the operations for which it is admirably adapted may be specially mentioned *fistula in ano*, which Dr. Dittel now invariably treats in this way. One end of the india-rubber thread is passed in the eye of a probe up the sinus into the bowel, then caught, brought out at the anus, and tied; it cuts out in a few days.

The patient on whom Sir Henry Thompson operated was a stout, middle-aged woman, who was suffering from an ulcerating fibro-cystic tumor (cystic sarcoma) of the right breast. She had had a lump in the breast for twenty years, but it caused her little inconvenience till two years ago, when it began to enlarge rapidly, and finally the skin over it gave way. At the time of the operation, the tumor was of the size of a large orange, and somewhat pendulous, the breast itself being wasted; it was crowned by a large, sloughy, fungating ulcer. The ligature used was tubular, about one-twelfth of an inch in diameter, the calibre of the tube being about one-third of this. A large nævus-needle was threaded with this and with a piece of twine (the use of which was explained afterwards) and passed under the base of the tumor; the elastic was then cut, the needle withdrawn, and the halves of the pedicle tied separately.

Sir Henry Thompson remarked, after the operation, that, although this was a very suitable case for the method adopted, it was not a severe test. The only accident that could happen was the snapping of the elastic when stretched; in that case, another length was tied to the twine, which had been passed under the tumor with the elastic and drawn by it along the track of the needle; otherwise, the twine was removed as soon as the ligatures had been properly tied. The best way to avoid the occurrence of this accident was always to use freshly-prepared elastic; if kept only a month, it was very liable to become brittle.

The skin over the tumor should be tightened just before tying, so that as little as possible might be included. Sir Henry added that, as that was the first time he had operated by that method, he had been anxious to conform in all respects to the practice of Dr. Dittel; but he thought that at another time he should be disposed to make a superficial incision through the skin along the course of the ligature, so that it would be in a groove and would not be liable to slip. He thought also that this would obviate the pain which Dr. Dittel said that patients sometimes experienced during the first two or three hours after the operation; in most cases, however, the pain was slight. This patient complained of pain, apparently not very severe, for about twenty minutes after she recovered from the chloroform. Dr. Dittel's paper in the *Allgemeine Wiener Medicinische Zeitung*, 1873, has furnished very full details respecting this mode of treatment.

INTUSSUSCEPTION (*The Medical Press and Circular*, November 26, 1873).—Mr. Jonathan Hutchinson details a successful case of abdominal section for the relief of intussusception.

The patient was a child, aged two years. The intussusception had commenced at the cæcum, and was of such length that its extremity, presenting the inverted ileo-cæcal valve, was extruded several inches at the child's anus. The condition had been one month in course of development; latterly the case had been treated as one of prolapsus, and attempts had been made to keep the bowel in place by means of a cork pad. Efforts to effect reduction by enemata having failed, the child was put under chloroform, and the abdomen was opened in the middle line below the umbilicus. The intussusception was then easily found, and as easily reduced. The after-treatment consisted only in the administration of a few mild opiates, and the child made a rapid recovery.

In three other similar cases the intussuscepted bowel could be easily felt by the finger in the rectum, and in all three, in spite of persevering treatment by injections, bougies, etc., the patients had died unrelieved. From the consideration of a considerable number of cases bearing upon the diagnosis and treatment of similar lesions, Mr. Hutchinson comes to the following conclusions:

1. That it is by no means very uncommon for intussusception to begin at the ileo-cæcal valve, and to progress to such a length that the invaginated part is within reach from the anal orifice, or even extruded.

2. That the prognosis of cases of intussusception varies much; first, in ratio with the age of the patient, and secondly, with the tightness of the constriction.

3. That in a large proportion of the cases in which children under one year are the patients, death must be expected within from one to four or six days from the commencement, and is usually caused by shock or by collapse from irritation, and not by peritonitis.

4. That in many cases it is easy, by estimating the severity of the symptoms (vomiting, constipation, etc.), to form an opinion as to whether the intestine is strangulated or simply irreducible.

5. That in cases of strangulated intussusception, whilst there is great risk of speedy death, there is also some hope that gangrene may be produced, and spontaneous cure result.

6. That in cases in which the intussuscepted part is incarcerated and not strangulated, there is very little hope of the occurrence of gangrene, and it is probable that the patient will, after some weeks or months, die, worn out by irritation and pain.

7. That the chances of successful treatment, whether by the use of bougies or by the injection of air or water, are exceedingly small, excepting in quite recent cases; and that if the surgeon does not succeed by them promptly it is not likely that he will succeed at all.

8. That the cases best suited for operation are those which have persisted for some considerable time, and in which the intestine is only incarcerated; and that these cases are also precisely those least likely to be relieved by any other method.

9. That in such cases, after failure by other means, an operation is to be strongly recommended,—the only circumstances likely to cause difficulty being (1) tightness of the impaction of the parts, (2) the existence of adhesions, and (3) the presence of gangrene.

10. That in very severe cases, or where the stage is greatly advanced, it may be wiser to decline the operation and trust to the use of opiates.

11. That the operation is best performed by an incision in the median line, below the umbilicus.

12. That in cases of intussusception in young infants (under one year of age) the prognosis is very desperate,

scarcely any recovering excepting the few in whom injection-treatment is immediately successful, whilst a large majority die very quickly; and that this fact should be held to justify a very early resort to operation in such cases.

SUBCUTANEOUS DIVISION OF THE NECK OF THE FEMUR FOR BONY ANCHYLOSIS OF THE HIP-JOINT (*New York Medical Journal*, December, 1873).—Dr. H. B. Sands reports the case of a man upon whom he has operated successfully for bony anchylosis of the hip-joint. The patient was twenty-five years of age, of fair constitution but somewhat irregular habits, and had suffered from a severe attack of articular rheumatism four years previous to the time of the operation. The right hip-joint was kept in a flexed position during convalescence, and subsequently remained rigid, the thigh being considerably abducted, and flexed on the pelvis at an angle of 110° to the vertebral column. The patient could not rest the right foot on the ground without assuming a crouching attitude, and could not walk without crutches.

The rigidity being found to be due to true anchylosis, the following operation was performed. A long, straight, narrow bistoury was thrust through the soft parts just above the great trochanter, and carried directly in front of the cervix femoris, so as to separate the soft parts from this aspect of the bone. A narrow saw was introduced along the track made by the knife, and the neck of the femur divided. It was then found necessary to sever the tendons of the adductor longus and the tensor vaginæ femoris, after which the thigh was immediately and readily extended to a right line with the body, and kept there by a weight attached to the foot; the patient being put to bed and confined there for six weeks, in the hope of obtaining bony anchylosis in the straight position. As it was found at the end of that time that the parts remained freely movable, he was permitted to get up and move around on crutches. There was a shortening of a quarter of an inch. He now walks quite well and steadily with a cane, a useful and satisfactory false joint having resulted.

INTRA-RECTO ABDOMINAL EXPLORATION (*The Medical Record*, December 1, 1873).—At a meeting of the New York Academy of Medicine, Dr. Charles Leale detailed a case in which he had raised a patient from a condition of profound narcotism from chloroform-poisoning by manual irritation of the solar plexus, the hand having been introduced through the anus and rectum. This treatment had been suggested by the results obtained in a case of like character from the use of electricity over the region of the solar plexus for the purpose of increasing the force of the respiration.

Dr. Benjamin Howard was not sure but that the same effect might have been produced by striking sharply upon the epigastrium where we can come into close proximity to the solar plexus; he thought that, although admissible, the use of both electricity and internal abdominal exploration for the purpose of irritating the solar plexus of nerves as a means of resuscitation should only be employed as a *dernier ressort*.

He was of the opinion that this method of examination promises to be an exceedingly valuable one in the diagnosis of tumors and displacements of the uterus, ovarian tumors, etc., and especially in the case of a stricture at the sigmoid flexure of the colon, where so much more can be learned by the touch than in any other way. It has, however, been followed by a strong tendency to incontinence of feces, and there are cases recorded in which perforation of the bowel and death have resulted from its employment.

Dr. Peaslee would place a check upon the indiscriminate use of this method of exploration. It is justifiable when a differential diagnosis is to be made between a

fibroid cyst of the uterus and an ovarian tumor, or between the latter and a tumor coming from above, as an enlarged liver or kidney.

STYPTIC COLLODION.—The following will be found a most useful formula:

Tannin,	2 oz.;
Alcohol,	4 oz., fl.;
Ether,	12 oz., fl.;
Soluble cotton,	1 drachm and 2 scruples;
Canada balsam,	1 drachm.

Dissolve the tannin in one part of the alcohol, and the ether with the Canada balsam; then add the cotton.—*Dublin Medical Press and Circular*.

A NEW DESTROYER OF THE HAIR.—Under the above title, Dr. Boettger, in the *Memorabilien*, says that we possess a new material for destruction of hair, of a most suitable description, in a mixture of one part of crystallized sulphurate of sodium with three parts of fine carbonate of lime mixed and reduced to a very fine powder. This mixture may be kept any length of time without alteration in well-closed bottles. When moistened with a drop of water and laid by means of the back of a knife on the part of the skin covered with hair, we in a few minutes find the thickest hair turned into a soft mass, easily removed by means of water. If it remains on the part long it will cause a slight irritation of the skin.—*London Medical Record*.

URETHROTOMY IN THE AGED (*The Lancet*, November 1, 1873).—Mr. W. L. Crowther advocates median urethrotomy with digital dilatation of the prostate in those persons who, from age, debility, or chronic cystitis, are unfit subjects for either lithotomy or the lateral operation. He says the operation produces only one shock, involves no cutting, either of the prostate or the bladder, is attended with the smallest loss of blood, entails no risk of subsequent hemorrhage, and makes the smallest demand upon the reparative powers.

MISCELLANY.

CHINESE ITEMS.—In the Eleventh Annual Report of the Peking Hospital (1872) in connection with the London Missionary Society, by Dr. John Dudgeon, are to be found some interesting cases of surgery in the treatment of the "heathen Chinese." There is a sect of the Tauist religion, whose practice of tenets contributes greatly towards finding work for the lithotomist. This sect ordains that all its disciples shall practise *kung-fu* or medical gymnastics with the view of strengthening the constitution and preventing disease. Many of their practices are of the vilest and most obscene description. One of the customs which a patient of Dr. Dudgeon learned was the introduction of a short lead bougie into the urethra at night, removing it in the morning. Lead bougies are also used for the cure of gonorrhœa, and in the impotence which Dr. Dudgeon avers sooner or later follows opium-smoking. They are of various sizes, and when about to be introduced are first rubbed with mercury. The patient in question had carried on the habit for ten years, and was convinced that he had thereby not only strengthened his system, but especially improved his complexion. One morning the bougie slipped into the bladder, from which it was then cut out by Dr. Dudgeon, who found it to measure two inches and a half in length and to weigh 256 grains.

Another patient had been in the habit of introducing a chopstick into the urethra; this also disappeared, and had to be cut out of the bladder. The Chinese have a simple way of settling a case of disputed parentage by a method described with great minuteness in the works on forensic medicine. The blood of the parent or supposed parent is to be added to that of the child in a basin of water. If the two coalesce, the case is beyond dispute; but if the drops do not draw together, there is no relationship. Dead relatives are recognized in a similar manner. It is satisfactory to learn that the benefits of vaccination are beginning to be felt and understood in Peking, and that there is in the town a shop for the "sale of anti-opium pills and the diffusion of knowledge."—*London Lancet*.

THE INCOMES OF METROPOLITAN HOSPITALS.—The most wealthy hospitals are the oldest. Bartholomew's, Guy's, and St. Thomas's head the list, with an annual income each of £40,000. Then comes the London Hospital, Whitechapel Road, with its income of £26,000 and vested funds of £200,000. St. George's and St. Mary's have each £15,000 a year. King's College, University College, and the Royal Free are in the receipt of £12,000 a year; the Charing-Cross, of £10,000; and the Westminster, of £7000. Out of sixteen general hospitals, the returns of fourteen show, in the aggregate, an annual income of £220,000. The incomes of the "special" hospitals depend mostly on voluntary contributions. It is thus curious to observe that the diseases which attract the most sympathy are those which cause the most suffering. Foremost among all stand the hospitals for consumption and diseases of the chest; six of these giving a return, as a whole, of £40,947 as the receipts of the year 1870. The institutions for diseases of children show an income of £21,000. Five lying-in hospitals, out of a list of nine, have together £7500; and the Fever Hospital is able to spend £12,500 a year. Cancer, perhaps the most dreadful malady that afflicts us, receives alone £7600 a year; and, after the hospitals for eyes, ears, legs, feet, and every part of the body, come the melancholy homes of the incurables, three of which together receive £34,000 a year. The united incomes of thirty-eight special hospitals are £137,000, making, with the general hospitals, a grand total of £357,000 a year; without counting those institutions whose incomes are not returned, those, like the *crèches*, which partake of the hospital character, or the dispensaries where the poor can get medicine and advice for nothing. At least one-third of this enormous sum is raised yearly by voluntary contributions. If, it is observed, the giving of money is a proof of charity, then the Londoners are a charitable people.—*British Medical Journal*.

F. MAYHEW writes to the *Lancet*, "Eli H—, aged about seventy-five years, is now living in a village near this town. Before he was born, his father made a vow that if his wife, then pregnant, should bring him a girl, she having had three in succession, *he would never speak to the child as long as he lived*. The child

turned out to be a boy. And now what is most strange and remarkable occurred. *This boy would never speak to his father*. Moreover, during his father's lifetime he would never speak to any one but his mother and three sisters. As soon as his father died, he being then thirty-five years old, his tongue was unloosed to every one, and he has remained an ordinary loquacious individual ever since.

"The verification of this strange story is easy enough. Every one in the village was acquainted with 'dumb Eli,' and numerous living witnesses remember his dumbness passing away."

NUMBER OF PHYSICIANS TO POPULATION.—Prussia has one physician for every 3200 inhabitants, Austria one in every 4355, Hungary one in 5492, while Russia has but one for 14,166 people. In the United States, according to the census of 1870, there is one "doctor" to about every 600 of population! Enough, one would think, to justify their being placed under some uniform national regulation.—*Med. and Surg. Reporter*.

NOTES AND QUERIES.

"DR. F. R. THOMAS.

"NITROUS OXIDE GAS!"

"Only office in the city where the entire practice is devoted to extracting teeth absolutely without pain!"

"Colton Dental Rooms removed to 912 Walnut Street. Fresh gas made daily!"

"DR. F. R. THOMAS."

This glaring advertisement may be seen in any of the Market Street city street-cars, conspicuously placarded above one of the windows. If we have not been misinformed, the individual so prominently brought before the notice of the public by this means stands well with his fellow-dentists. Have all the members of the dental profession this liberty accorded them with their diplomas? Is dental surgery a department of the science of medicine, or is it a trade, a business, without a code of ethics?

We should be pleased to hear the status of the dental profession (for such it is termed) defined, in the present day of doubt and uncertainty. If such things be permitted, whither, indeed, is dentistry drifting?

Respectfully, yours,

DENS.

Answer.

Dentistry has been a business; at least we are not aware of the existence of any code of ethics. Whither it is drifting it is hard to say. The editor of the *Dental Cosmos* thinks it is drifting into a profession. *Quien sabè?*

TO THE EDITOR OF THE MEDICAL TIMES:

SIR,—An article which appeared in your journal December 6, under the title of "Tinea Sycosis," has suggested the following question, which I should feel obliged if you could answer for me:

Do the appearances given in the article referred to afford *unmistakable* evidence of a parasitic disease of the hair-follicles?

Yours, etc.,

SUBSCRIBER.

Answer.

TO THE EDITOR OF THE MEDICAL TIMES:

SIR,—In reply to your correspondent "Subscriber," I would say that microscopic appearances alone can afford *unmistakable* evidence of parasitic disease in cases like those to which he alludes.

Parasitic sycosis is one of the rarest of skin-diseases, and, when it exists, a microscopic examination will almost invariably bring to light the characteristic fungus, which is always abundant.

I am, sir, etc.,

CONIDIUM.

SATURDAY, JANUARY 10, 1874.

ORIGINAL COMMUNICATIONS.

PRURITUS HIEMALIS—AN UNDESCRIBED FORM OF PRURITUS.

BY LOUIS A. DUHRING, M.D.,

Clinical Lecturer upon Diseases of the Skin in the University of Pennsylvania.

IN the present paper I wish to describe and direct attention to a certain affection or condition of the skin of which there is no mention in any of our treatises upon cutaneous diseases or elsewhere. Quite a number of examples have been brought to my notice within the last few years; in some instances the trouble being of such severity as to call for careful investigation and subsequent treatment. Moreover, the affection about to be described has never, so far as I am aware, been separated from several other conditions of a similar nature with which it has heretofore been grouped. But the symptoms, course, and cause of the disorder appear to me to be so clearly defined as to merit a distinct and separate consideration.

The trouble varies much in degree, at one time being of the most serious inconvenience to the patient, and at other times being of so mild a character that medical advice is not sought. Thus, it may be so slight as scarcely to deserve the name disease, or, on the other hand, so severe that the individual is rendered most miserable by it. When of a mild type, for reasons presently to be mentioned, the patient endures the condition without undergoing treatment, for experience has taught him that the condition is a temporary one, and will, in due time, subside spontaneously. Previous attacks have taught him that sooner or later, in the course of a few weeks or longer, his skin will again be in a normal state, and this occurrence of the change to health is anxiously looked for. The skin sooner or later rights itself without treatment, and the patient remains free for a certain period. But, on the other hand, it may occasion such discomfort and distress that the person anxiously consults his physician, and willingly submits to any treatment, with a view of obtaining at least temporary relief. The symptoms may be so annoying and disagreeable as to render existence most unhappy for the time being. For the reason, then, that it is a trouble by no means rare, as well as one frequently requiring attention from the physician, I shall offer the result of my observations. I have designated the affection *Pruritus Hiemalis*, for reasons which I think will appear satisfactory.

Symptoms.—The affection consists in a peculiar state of irritability of the skin, which manifests itself in the autumn or even as late as the winter season. Generally it first makes its appearance with the advent of our cool October weather, or at about the time of frost. It may, however, not be noticed until later in the season—as late as

December. In Philadelphia it commonly occurs towards the latter part of October, and continues usually until the cold weather has been thoroughly established, or even through the winter. Its duration is variable. In some cases it lasts but for a few days or weeks, and then disappears entirely. In other instances it remains present persistently for several months or longer; but it is never present after the cold weather has passed. With spring it always vanishes, to be absent at least until the succeeding autumn. It is rare, however, to observe it continuing in any marked degree through the entire winter. It is an affection of the cool weather only, and more particularly of the fall and winter season. It is never present in the summer months. It is found upon individuals of all ages, from childhood to old age. No particular period of life appears to be more susceptible than another. I have never met with it in young children, nor indeed much before the age of puberty. It occurs in both sexes in about the same proportion. It may exist upon any part of the body, though prone to attack certain regions in an almost invariable manner. It is confined, not entirely, but to a great extent, to the lower extremities, and it is here that it shows itself typically. It occasionally is found upon the arms, and more rarely upon the trunk, but never to the same extent and degree as upon the thighs, buttocks, and legs. The hands, feet, face, and scalp are never involved. Its common seat is upon the inner surface of the thighs, about the knees, in the popliteal space, upon the calves of the legs, and around the ankles. It affects the non-hairy portions of the limbs rather than the hairy parts. The outer surface of the thigh and the region of the tibia are more rarely involved than, for example, the calf of the leg. The calves of the legs are favorite localities for the trouble. It attacks both lower extremities symmetrically. Occasionally only the ankles and calves are affected, but in most cases it extends well up upon the thigh. It is not a localized affection,—that is, cannot be said to exist upon any given portion of the body exclusively. The sensation may be most intense here or there, as the case may be, or it may move from time to time from one locality to another. But the same regions are usually attacked day after day, and the symptoms remain there until they disappear entirely; and hence, although it cannot be said to be localized, yet, if present at all, it is almost invariably to be found upon the regions which I have particularized.

The affection may be said to be characterized by a certain itching of the skin, more especially of the lower extremities, which comes upon the individual rather suddenly, in the course of a few days, during the autumn or early winter, and which may be described as an itching, smarting, tingling, burning sensation, as though the person were clothed in new flannel or woollen-wear, and the same were rubbing and chafing the skin. The amount of irritation present varies with different cases, and may be either very slight, so as barely to attract attention, or it may be so severe and troublesome as to cause the sufferer very great annoyance and distress. It

possesses one peculiarity which is striking, and generally present,—namely, the tendency to become aggravated towards night. It is always worse in the evening than at any other period in the twenty-four hours, and in many cases is present only at this time. In the mild form it is scarcely noticeable during the day, coming on with evening, and continuing through the night until sooner or later the patient retires and falls asleep. It is when taking off the clothes, at night especially, that the itching is most noticeable and severe. At this time the desire to scratch and rub the affected parts is almost irresistible, and the person usually gratifies this desire either until some relief is obtained or sleep terminates the suffering. A certain amount of relief follows severe scratching, and a marked burning sensation takes the place of the itching, which is far more grateful to the feelings of the patient. According to the amount of disturbance and the irritability of the cutaneous nerves, will the sleep be more or less interfered with. At times the skin is so excited and disturbed that the person obtains but imperfect rest, and at least the earlier part of the night is passed in scratching and in making cooling applications of one kind or another to the parts. In other cases the itching is simply unpleasant and annoying upon retiring, but not sufficiently so to interfere with sleep.

Upon awaking in the morning, a little of the pruritus may still exist, but usually it has quite subsided, and no further thought is given the subject until the following evening, when the same symptoms reappear, and are exactly repeated. In this manner it continues day after day, with but slight intermission, until, at the end of an indefinite period, it gradually vanishes. The patient now remains free of it until the next autumn, when in all probability it will recur and run a similar course. It may relapse in this way year after year, or at the end of the first attack it may disappear, not to return. It is apt, however, to attack the same individual several seasons in succession, and then remain away permanently. It may also continue through a lifetime.

There is no *primary* eruption of any kind connected with the affection, either at its commencement or at any time during its course. This is an important point to be remembered in connection with the diagnosis. If the skin be minutely and carefully examined at the beginning of an attack, we see nothing indicative of disease, or anything, indeed, which would enable one to account for the itching present. Inasmuch as the condition is always most marked and typical about the lower extremities, I shall describe the appearance of the skin as seen in a well-defined case the first day of its existence, for later the appearances are quite different, and call for a separate description. When the trouble is first noticed, then, the skin looks quite healthy, with the exception that it is apt to be somewhat dry. The epidermis seems normal, and there is no desquamation. The skin is neither hot nor hyperæmic. The hair-follicles are neither inflamed nor obstructed, and appear to be in order. There is no accumulation of epidermis or other matter about

their openings. They are not prominent nor visibly altered. In fact, after close inspection, it is impossible to distinguish any sign of derangement in connection with the follicles, which parts, upon first thought, we might imagine to be the seat of the disorder. Here and there an inflamed follicle may exist, but this condition, however, occurs only occasionally at this stage of the trouble.

The condition of the sudoriferous glands it is difficult to determine, further than that they do not work very actively; but there is no reason for supposing that they are in any serious way deranged, or more so upon these localities than upon other portions of the body. There is no perceptible functional derangement of the skin. Neither is there any organic alteration observable. The subjective symptoms, which the patient communicates, alone convey any idea of the condition.

But if the case be seen several days or longer after the first symptoms, the skin looks different. Certain secondary changes now exist which, if error is to be avoided, must be viewed as such. For to regard these *secondary* lesions, which at this stage are present, as the *primary* lesions of the affection, would certainly be misleading as to the nature of the disorder. It must be remembered, too, that this stage is the one in which cases are usually seen, for advice from the physician is rarely sought before the trouble has existed for some time.

The skin now may be rough and harsh, resembling xeroderma or mild ichthyosis. Many of the hair-follicles are red and more or less inflamed and irritated, with an accumulation of epidermis and sebaceous matter about their openings. Many of the hairs are also torn and broken off short, close to their follicles. Here and there, or over a considerable surface, the whole skin looks red and irritated, as though it had been well rubbed and scratched. Upon close inspection, the epidermis bears unmistakable evidence of having been torn and wounded. The marks of the finger-nails are everywhere to be seen, often in the form of long streaks up and down the limbs. In fact, all the phenomena just detailed, which are so marked and prominent, are produced solely by the hands of the patient. They are all *secondary* lesions. They are the *results* of the pruritus. To view them as the primary lesions would give a very wrong idea concerning the nature of the trouble. The line of distinction between the primary and the secondary symptoms must be clearly drawn. The primary symptoms are subjective alone. The secondary symptoms, those usually seen clinically, are both subjective and objective, the latter being an artificial product, caused by external irritants.

Such is a description of the disorder as I have encountered it through a number of seasons, and which it has been my pleasure to study and note as opportunity for observation upon new cases offered. There are other points of interest to be mentioned, which it will be more convenient to consider under the various heads of Etiology, Diagnosis, and Treatment.

Etiology.—In turning our attention to the cause of this trouble, there are a number of facts which I

have observed and noted, and which now present themselves for consideration. From these alone we shall be obliged to draw our conclusions, be they satisfactory or not, for they constitute our only aid and guide in endeavoring to ascertain the cause. One important observation, which has been universally noted, determines the fact that the condition is intimately associated with atmospheric changes. It is emphatically an affection of the cold weather, at the commencement of which it invariably establishes itself. With the first decided and permanent change of the fall season, with the first ice, it is usual to note its presence.

Now, this fact is observed not in one, but in all cases. And here it must be remembered that the observations which I am about to detail refer exclusively to the latitude and climate of Philadelphia. What the conditions may be a thousand miles north or south of this point, I am not prepared at present to state definitely; but, from memoranda in my possession,* the affection also manifests itself very commonly in more northern latitudes. In southern countries it is unquestionably more rare, if indeed it occurs at all. But upon this point I have no reliable data. In England, inasmuch as no writer upon the subject of diseases and affections of the skin has referred to the condition, we are warranted in assuming that it is very rare. As a student of dermatology I passed several months of the autumn and winter season in London, attending daily large clinics of cutaneous diseases; but I do not recall ever having encountered any cases of the trouble, notwithstanding every variety of disease and alteration of the skin presented itself. The works of English writers upon dermatology do not so much as allude to its occurrence. My experience in France and Southern Germany, especially in Vienna, extending over a period of a whole autumn and winter season at the two largest daily clinics for diseases of the skin in the world, was similar to that in London, the condition never having been noticed. Nor do the German writers mention its existence in their treatises upon cutaneous disorders. But to return.

It occurs in persons otherwise in excellent health. The various other functions of the economy appear to be in perfect order. The nervous system, so far as can be ascertained by symptoms, shows no signs of general impairment or derangement. The bowels are not constipated, nor are any of the secretions apparently abnormal.

The affection is found upon people of all ages, and is not common to any particular period of life. It is observed upon the young as well as the old. As already stated, it occurs in both males and females. At times it is seen in several members of the same family. It is found equally among those who live in luxury and comfort, and those dwelling in poverty. It occurs among the black race. It is as common in the houses of the wealthy as it is in our almshouse. No class of society is exempt. It is not a condition caused, or in any way influ-

enced, by neglect of person or by inattention to cleanliness, for it exists in no greater proportion among the dirty and unwashed than among the clean. It is as frequent among bathers as among those who never use the bath. It is present both among those who bathe in cold and those who bathe in warm water. It is as common among those who employ the bath every day as among those who use it more seldom. From these facts it will be noticed that water possesses very little influence in either its prevention or its causation.

Here it will be in place to refer to a series of investigations which I have made during the past month (December). Feeling assured from previous experience that the condition was in all probability to be found among all classes of a community, I was induced to examine a large number of people. My investigations were undertaken with a view of ascertaining to what extent the disease existed; also, if examples were found, for the purpose of studying them and corroborating previous observations. The results of my labors may be summarily stated as follows:

The wards of the Philadelphia Hospital (Blockley) and the Almshouse were selected for the purpose.† Both sexes, all ages, as well the cleanly as the uncleanly in personal habits, were included. Four hundred and twelve persons were examined. Of this number two hundred and twenty-seven were men, and one hundred and eighty-five were women. They consisted of cases from the hospital who neither had been nor were confined to bed, and also paupers from the almshouse.

Out of the whole number, four hundred and twelve, twenty-two cases of the disease were found. Fourteen were among the men, and eight among the women. Each of these cases was carefully examined, and the diagnosis fully established. Some of them were slight, while others were more severe; but there was no difficulty in recognizing the trouble in any of the cases. None of them, however, were of such severity as several of the cases which have come under my notice in private practice. Among the patients examined there were examples of pruritus whose exact nature seemed somewhat doubtful; these were excluded.

From these figures it will be seen that upon an average the condition exists in one out of every twenty persons who are otherwise in ordinary health. Whether this ratio holds good among the upper classes, who are better cared for and nourished, we have no means of determining positively at present, but there is every reason to think that it exists quite as frequently.

The disease is not caused by any peculiarity in the clothes worn. This is a point about which I desire to speak more at length, for there exists an impression in the minds of some that the condition I have been describing is simply an irritation of the hair-follicles and skin, due alone to the coarse, irritating undergarments usually assumed at this season of the year. Flannel and woollen goods, especially,

* I am indebted to Dr. Wigglesworth, of Boston, for certain notes relating to the affection as there noticed by him.

† My thanks are due to Dr. Linn, Resident Physician to the hospital, for the many facilities received in pursuing the investigation.

have been cited as being among the direct causes of this pruritus. But investigation and accurate observation, I think, will prove the error of this idea, which has obtained credence with some. Patients themselves at first are likely to attribute it to such causes, but subsequent experience proves even to them that such is not the case.

Now, neither flannel, woollen-wear, nor rough goods of any description, are the direct causes of this form of pruritus, but when they are worn they always tend greatly to aggravate the condition. In fact, not only do such garments increase the itching, but patients find it intolerable to use these fabrics, on account of the irritation which they provoke. The skin is so excited that such goods are unbearable, and the patient soon learns to shun them once and forever. Clothing, whether new or old, whether of wool or of cotton, then, is not the primary cause. For here also clinical experience proves that the affection exists upon persons who have never worn woollen or other rough undergarments of any kind. It occurs in those who are most careful in avoiding harsh irritating underclothes, and also in those who wear only the finest linen next to the skin.

External irritation, therefore, has no share in the primary cause.

Diagnosis.—We come now to speak of the diagnosis; and here I must state that the trouble we are considering has manifestly been confounded with other conditions of a similar character. It is by no means a rare disorder. It is to be seen every season at our clinics for diseases of the skin, but it has been associated and confused with other diseases to such an extent that its individuality has been lost. The fact, moreover, that it may occur in so many grades of severity, from the mild to the most aggravated type, has tended to render its true character somewhat obscure.

The affection primarily is a pruritus of the skin. By the word pruritus I mean a functional disorder of the skin unattended by an eruption or breaking-out, and whose only symptom is itching and other like sensations. In the trouble we are discussing, then, there is no rash or change of any kind in the texture of the skin. The symptoms are simply itching, burning, and smarting of the skin, unaccompanied by any visible cause. Such is the primary condition of the disease. The secondary stage shows us these same symptoms present, and, in addition, other signs which must be here referred to. With the advent of the pruritus the patient at once begins to scratch, the desire being so strong that it is not to be resisted. The rubbing and scratching are often inordinate, and this process continued night after night, for perhaps several hours at a time, necessarily irritates the skin. The epidermis and hair-follicles suffer first, and about the openings of the latter a slight congestion is soon induced, which is kept up by the constant renewal of the cause. The hairs are broken off, twisted, and torn by the violent scratching and rubbing. Many of them are completely destroyed, and usually in a short time certain parts of the limbs are entirely devoid of hairs.

The follicles likewise are often obliterated, leaving a smooth, bald surface, which remains. The appearances at this stage may be manifold. The skin may be harsh, dry, and rough; or it may be smooth and natural. This varies according to the general condition of the skin. Frequently a certain amount of desquamation is present, covering parts of the limb as fine detached bits of epidermis. Scratch-marks can almost always be seen now if looked for, and generally they are noticeable even upon a casual view. Often they are observed as long streaks showing the tracks of the finger-nails. Signs of blood are more rare. Here and there, however, torn and lacerated follicles are seen, some of which may show a small quantity of fresh or dried blood. In some cases congested follicles appear in numbers; they are red, and appear acutely deranged. They may be somewhat obstructed with epithelium and epidermis, or they may assume the look of little elevated points. The intervening skin is generally more or less red and irritable. In other cases, in place of these symptoms nothing abnormal is to be seen, the scratching having little effect in producing artificial lesions.

All these visible symptoms, then, must be considered as artificial, as caused by the operations of the patient in the endeavor to get relief. They subside rapidly upon the cessation of the scratching or other mechanical irritation, whatever it may be, and are soon lost sight of, remaining away until irritation causes them again to appear.

There are two diseases with which pruritus hiemalis may be confounded. I refer to lichen pilaris, and prurigo as understood in this country.

Without entering into any differential diagnosis, I shall point out, in as few words as possible, wherein pruritus hiemalis differs from the two conditions just enumerated. The lichen pilaris of authors, as the name indicates, is a certain disease involving the hair-follicles of the skin alone. As described by several writers of the present day, it consists in an accumulation of epidermis and sebaceous matter about the openings of the follicles. This state of disease is the primary and only one. Itching may or may not be present; frequently it is absent. Lichen pilaris is commonly seen upon those who do not bathe, the masses of epidermic product being permitted to remain about the hairs, where, by degrees, a slight conical elevation or papule is formed, the hair or its stump perforating the centre of the accumulation. The affection is usually located upon the thigh, and especially the outer surface, where it is, as a rule, the most marked. Other parts of the body may also be affected in like manner. It is a condition speedily relieved in the majority of instances by the free use of hot baths and soap, which, by mechanically removing the obstruction of the follicles, permits these organs again to assume normal action.

From these few general points it is plain that there can exist no connection between lichen pilaris and the pruritus which I have attempted to describe. It will, I think, be seen that they are totally different conditions, having in reality little or nothing in common excepting that they are apt to occur at

about the same time of year; but other affections of the skin are likewise prone to show themselves in the fall and winter, and this, therefore, must be regarded merely as coincidence.

Lichen pilaris has its favorite seat about the outer surface of the thighs. Pruritus hiemalis occurs anywhere upon the limbs, with predilection for the less hairy parts. Lichen pilaris never occurs in the popliteal space. This is one of the common localities in which to find pruritus hiemalis. Many other differences there are, which will be noticed by comparing the symptoms of the two disorders side by side. I dwell upon this subject, because it has long since occurred to me that the pruritus we are discussing, particularly the secondary stage, has been associated with lichen pilaris. In many instances this undoubtedly has been the case.

With *true* prurigo, the prurigo of Hebra, we have the formation of distinct plastic papules: hence this pathological lesion alone is sufficient to distinguish the two affections.

Itching, scratching, excoriations of the skin, and other like symptoms due to the presence of pediculi, are here referred to merely for the purpose of mentioning that they have no share whatever in the pruritus we are discussing. They may possibly exist coincidentally at times, just as pediculi are liable to be found upon any person, but they are never the cause of the disease. No more need we even suspect the presence of any of the vegetable parasites as a cause.

Pruritus, or itching of the skin, is a term under which are included many varieties. The word pruritus, used alone, simply informs us that there is an itching of the skin, but fails to state the nature or cause of this sensation. Pruritus may be produced by many causes, due to derangement or disorder of one kind or another in the cutaneous surface. This subject interests us here only to the extent that we may be able to distinguish the variety which we have designated "*hiemalis*" from the many other kinds which are encountered.

Once recognizing the trouble as a pruritus, it seems as though there could be little danger of confusing it with any of the other forms. When all the symptoms are taken into consideration, there really exists no other variety which runs a like course with similar symptoms. The fact of its being an affection of the fall and winter season only, stamps its individuality at once. Its almost exclusive habitat—the lower extremities—is another peculiarity which it is important to remember. The particular parts of the limbs almost invariably involved also must be borne in mind. The almost entire freedom during the day, and the constant attack towards night, and especially upon the taking off of the clothes, are also characteristic.

Treatment.—With reference to the treatment of this form of pruritus, my experience has been confined to some twelve or more cases which have from time to time been under my care; about half being in private practice and the remainder in dispensary practice. I shall briefly give the results of the various remedies employed. First, as to water.

Plain water-baths, whether hot or cold, do not appear to exert much permanent influence over it, but, of the two, hot water more often affords some relief. The cold douche to the parts frequently gives temporary ease, and allows the patient an opportunity of getting asleep. A course of continuous daily bathing in cold water, kept up for the season, does not seem to exert any favorable influence. A warm bath daily, however, upon going to bed, will often insure the patient more comfort. Turkish baths have been employed, but with no success in relieving the symptoms. A course of thorough soaping with soda-soap, and afterwards a warm plain bath, has also been used, but with no better result than the simple bath. Where the scratching and other secondary lesions are marked, this course of treatment is not to be recommended, for, the skin being wounded, the soap together with the friction only increases the already irritable skin. Better success, however, may be found in the use of the alkaline bath, which affords more permanent relief than any other treatment with which we are familiar. The bath is prepared by dissolving four ounces of the carbonate of soda in a full-sized bath-tub of warm water. The water should be sufficiently hot to allow the patient to remain in it without feeling at all chilly. The patient should stay quietly immersed in the water for twenty minutes. Upon getting out of the bath the parts should be slowly and gently dried by patting with a soft dry towel. No rubbing or friction should be indulged in, for, though gratifying at the moment, the after-effects show the skin to have been greatly excited and the trouble aggravated.

The bath should be taken in the evening, just before retiring. The patient should wear a light night-dress, and sleep as coolly as possible; the bed should be hard,—preferably a mattress,—and the covering just sufficiently warm to prevent a feeling of chilliness. The sheets should be of soft muslin or linen.

During the daytime, linen, muslin, or the so-called Canton flannel underclothes should be worn, and all garments of a woolly nature discarded. Everything must be done to soothe the irritable skin in all possible ways. Heated rooms and hot stoves must be avoided. During the evening a walk in the cool air will be much more grateful than the warm room; for if the itching be inordinate in a hot, dry atmosphere, and the patient suddenly go into the open air, it will be found that the symptoms will to a great extent subside. As is well known, these remarks apply to almost all forms of pruritus, but they are especially applicable to the kind I am describing.

As with other varieties of pruritus, simple rubbing, or scratching with the finger-nails, unless it be excessive, does not produce any great amount of laceration of the skin. The patient may scratch quite severely at night, and yet, upon awaking, find very little trace of the performance. This remark supposes the case to be a mild one. If the case be severe, the scratching will necessarily be violent, and the skin will then show signs of the destructive work which has been done.

With reference to internal treatment I have little to suggest, for, though preparations of iron and arsenic have been employed in certain cases, unfortunately there is nothing favorable to report.

From what has been said, it will be evident that the affection must be regarded as a pruritus. The symptoms from which we are forced to deduce our conclusions are purely subjective, and hence, unless we venture into the domain of theory, our remarks concerning the pathology must soon come to a termination.

In the present state of our knowledge very little is positively known concerning the nature and pathology of neuroses. In the condition described, further than that it is a pruritus of a certain kind, accompanied by a series of well-marked and constant symptoms, our information does not permit us to go. What changes take place in the skin in order to give rise to these symptoms, it is impossible to ascertain. An irritability of the skin, taken as a whole, unquestionably exists, but in what particular organs or parts the derangement occurs it is not possible at present to determine. To suggest that the disease has its origin and is located about the follicles, and that all the symptoms may be referable to derangement of these organs, is a theory attractive and perhaps plausible, but in the present state of our knowledge more definite information is required before adopting this view.

In brief, to venture further in theory as to the exact nature of our trouble is not consistent with the tenor of this communication. Positive knowledge upon such points relating to anatomical and pathological changes is alone desirable, if we would advance our subject in a scientific manner.

ACCIDENTAL HEMORRHAGE DURING PREGNANCY.

BY H. LEAMAN, M.D.

ACCIDENTAL hemorrhage, occurring during pregnancy and preceding labor, embraces all hemorrhage which may take place from accident of any kind, excluding placenta prævia or unavoidable hemorrhage, as well as all effusions of blood which may occur of a vicarious character in other tissues and organs.

It has its seat in the vascular system of the uterus or in that of the fœtus. It may occur early in pregnancy, in the form of effusion from the general uterine surface; later, the hemorrhage is most commonly due to a separation of the placenta from its uterine attachment, or to a rupture of the umbilical cord. Effusions are due to an increased flow of blood to the organ, which begins with conception. The separation of the placenta may be brought about by mechanical violence, and by vascular or nervous derangement. A rupture of the cord may be due to a shortness, an irregular distribution of the vessels, or a degeneration of the envelope of the umbilical vessels.

The hemorrhage may be open, the blood finding its way between the membranes and uterus, and

appearing externally. In concealed hemorrhage the blood may be retained beneath the placenta and within its circle of attachment; it may be retained between the membranes and the wall of the uterus; or poured into the amniotic cavity,—intra-amniotic.

Dr. Meadows gives the statistics of Dr. Churchill, as follows: in 257 cases of accidental hemorrhage 34 proved fatal, or one in seven; while of 292 cases of unavoidable hemorrhage 79 proved fatal, or one in three and a half; and out of 365 cases of post-partum hemorrhage 25 proved fatal, or about one in fourteen.

Cazeaux says that hemorrhage occurring early in gestation is more serious to the child; in the latter part, to the mother; especially dangerous to the mother between the seventh and eighth months. That the life of the mother is in little danger in the early months of gestation seems to me to be sustained by experience, as well as by the very common practice in our day of interfering with the product of conception either by drugs or instruments. One case came under my notice in which the woman was suffering a severe hemorrhage, from which she readily recovered. She confessed that it had been brought on by the use of an instrument in her own hand, and that it was the seventh time she had succeeded. She showed us an old well-worn Simpson's sound. Very recently a similar case has come under my notice, and such cases, I believe, are not new. When death does result from these cases it is generally due to a typhoid or inflammatory condition. Hemorrhage occurring within the last three months, however, is an entirely different thing. How to act under these circumstances, when two lives are hanging by very tender threads, and when we may be the means of cutting one or both, requires all the wisdom we can command, as well as the inspiration of an Hippocrates. To illustrate my subject, it seems preferable to give the narration of a case which came under my care in the early part of the past spring.

Mrs. Anna McBride, aged 32 years, the mother of six healthy children, pregnant with her seventh, was taken with a slight hemorrhage between the fifth and sixth months of gestation,—February 21, 1873. Two or three days' rest relieved her entirely, and she went about her household duties as usual. These were not of the lightest character, such as doing the washing for the entire family, and carrying it to the top of a three-story house to dry, cooking for boarders as well as for her own family. On the 27th of April, 1873, four o'clock A.M. Sunday morning, I was again called to see her with a similar hemorrhage, just two months and six days after the previous attack. The flow had commenced while she was asleep. When I saw her she was perfectly comfortable, and was losing moderately. She was positive that she was six weeks from her full time, and was certain that she felt the movements of the child. As she had no pain, I gave her directions to be perfectly quiet and keep her bed. I saw her again at nine A.M. She had not changed in any respect; she had no pain, and reassured me that she felt the movements of the child, and that her time was not yet up. I ordered her half-drachm doses of the fluid extract of ergot every hour or two, with directions to send for me at once if there was any increase of the flow. She sent for me at 12 noon; not being in, and no one present realizing the danger, she remained without medical help until I reached her, at half-past one. She

was then exsanguineous, gasping for breath, her pulse flickering. She had bled until there was just enough of blood remaining to keep the heart beating. The tampon was immediately applied, and the little of life that remained was carefully fed with milk, whisky, and air. I watched her and remained with her until four o'clock P.M. At six o'clock she had scarcely reacted any, and was still in a state of syncope, although she had lost not a drop of blood since the application of the tampon. It was not until late in the evening that the pulse became regular and her consciousness restored. She was well fed during the night with whisky, eggs, and milk, and was undoubtedly stronger when I saw her on the morning of the 28th. There was no evidence of hemorrhage externally, and her improvement indicated none internally. At this time Dr. Deal saw her with me, and agreed that it was prudent to gain a little more strength before delivery should be undertaken. The tampon was allowed to remain, but, as there was apparently some distress from tension, it was slightly relaxed. At one o'clock, finding her weaker, Dr. Deal was again called in, and it was agreed that to terminate her labor was the best we could do. The membranes were broken, and delivery accomplished by turning. The placenta came away with the child, and there was no blood accompanying it. The child was dead, and the cuticle over the entire surface of its body came off with the slightest pressure, as if it had been blistered. The womb contracted firmly, and, with the hand kept upon the uterus, and all assistance we could give her, she expired an hour and a half after delivery.

There was no placenta prævia; the bag of waters could be distinctly felt in the mouth of the womb. It was believed to be most likely a detached placenta, and probably brought about by the heavy duties of her household. The first flow two months previous was most likely due to a very slight separation of the placental surface. The child was a full-sized male, and its development had been very recently interrupted.

How was it possible to know before nine o'clock A.M. Sunday morning what ought to have been done? Delivery before that time at the peril of the child might probably have saved her. After the profuse hemorrhage between twelve and one o'clock, there was no time at which delivery promised much. Here was moderate hemorrhage becoming profuse in a few hours. How is it possible for us to know when this change is likely to take place? The treatment of moderate hemorrhage before labor, as laid down by M. P. Dubois, and as given by Cazeaux, is as follows: "Horizontal position, absolute rest, fresh air, cool acidulated drinks, restricted diet, venesection; if there are any symptoms of plethora, empty the bladder and rectum. When the hemorrhage is profuse, the same measures, except venesection, are to be used, with the addition of one-half drachm of ergot, divided in three doses, at intervals of ten minutes. And if these are insufficient, apply the tampon or perforate the membranes."

Can we separate the treatment in this manner? Where can the dividing-line be drawn? From four o'clock A.M. until nine A.M. the flow was undoubtedly moderate; yet within the next three hours it had become profuse. What is best to be done in such cases must of course be left largely to the skill, foresight, and judgment of the physician; and yet might we not arrive at something more definite in the way of treatment?

The treatment of hemorrhages early in gestation,

such as those already referred to as being rarely fatal, is accomplished almost entirely by rest. The gradual enlargement of the vessels, with the increasing size of the uterus, augments the danger with each succeeding month. During the last month, according to Cazeaux, the danger is again diminished, owing to the more easy dilatation of the neck.

THE OPIUM-HABIT.

BY W. D. MARTIN, M.D.,

Pennsylvania Steel-Works.

OPIUM-EATING is seldom spoken of by lecturers in our medical schools. In medical journals, also, the subject is rarely mentioned; and, in consequence of the adroitness of the votaries of opium in concealing a bad habit, the physician in private practice scarcely ever confronts this vice. There are few, therefore, who are familiar with the subject,—one of much importance, now that the use of opium as a stimulant is greatly on the increase in the United States. I have noticed its abuse by physicians, female teachers, servant-girls, and even by farmers' wives.

Seven cases have come under my observation; and I relate the following, a typical case, where, as in the majority of instances, opium was used exclusively as a stimulant:

Early in the year 1867, a gentleman, 28 years of age, in good health, by profession a civil engineer, began the regular use of opium as a stimulant, having for a year before that time merely tampered with it on occasions of despondency and gloom. Engaged in a survey of public lands in remote and lonely situations, his spirits became depressed, and it appeared to him that solitude and misfortune were to be his lot. Under these circumstances he occasionally indulged in alcoholic stimulants, and after a time in such excess as to materially interfere with his duties as an engineer. Realizing this at last, and having read of opium and its extraordinary powers as a stimulant, he had recourse to it when unusually depressed in mind, and finally became habituated to the daily use of the drug.

Beginning with gum-opium, he occasionally rolled up a small piece and swallowed it; but, experiencing unpleasant digestive derangements, pressing constipatory effects, and intense itching of the skin from the use of opium in that form, he employed the salts of morphia. He carried the *sulphate* in a little vial, and used from time to time the indefinite quantity he found necessary to calm his perturbed mind: thus he became addicted to a stimulant, the abuse of which finally became indispensable to a comfortable existence.

As an antidote to whisky he found it perfect. It soon ceased to disturb digestion; it did not flush his face or proclaim itself on the breath; his bowels, though constipated, appeared conveniently so, as he was not bothered with their evacuation more than twice a week, and he could comfortably retain his urine for twenty-four hours. His muscular system was steady, he slept well, his mind was calm and satisfied under all circumstances, and he experienced a strange and agreeable buoyancy, a self-reliance, and a nonchalant happiness all the time.

When I first saw him he had used morphia for four years, had experienced its pernicious effects, and had made several attempts to abandon the habit. At this time he found that, notwithstanding a considerable retrenchment of his daily allowance, he was using eight

grains of the sulphate of morphia per diem, or one drachm per week.

He was sallow, with hands without moisture, and his finger-nails were brittle, his eyes were dull, his mouth and lips dry, the secretions were scanty, the bowels constipated, and he was occasionally subject to temporary, but distressing, bilious diarrhœa. In addition to this, his hair was dry and husky, the skin inactive and itchy, and he had inveterate pityriasis of the scalp.

In disposition he was inert, lazy, forgetful, disposed to sleep, which was uncertain and troubled by dreams, in which he started up in bed, his mind a prey to vague terrors. On this account he often used chloral at night, which, though it produced sleep, exacted an equal number of nights of wakefulness when he discontinued its use. He could not take stimulants for some days after chloral, on account of an intense erythematous blush of the skin which invariably followed, and caused a violent beating of the carotids against his pillow that effectually banished sleep. The sexual function was impaired; and finally he was anxious, nervous, and desirous of freeing himself from the power of opium.

Now, what are we to do for such a case? Diminish very gradually and circumspectly the amount of opium used until the system can do without it? This is quite impracticable, if not impossible, unless the patient is under restraint. Shall we suddenly suspend the poison and sustain the system? This treatment has been employed with success, but it results in great suffering, is also dangerous, and, according to my observation, will not do for bad cases, which are so debilitated after recovery from opium-poisoning that they fall easy victims to pneumonia and kindred affections.

With reference, however, to the train of symptoms to be expected when from any cause opium is suddenly withheld from a person accustomed to its use, I quote from Dr. Flemming, of Birmingham, England, whose method of treatment I have followed, and who treated his cases by suddenly suspending the drug, as recommended by Dr. Christison in 1850:

"Having put a stop to the indulgence, you must be prepared for a great increase in the mental as well as in the bodily suffering of the patient. He is a prey to intense depression; he is sleepless, excessively irritable, full of alarms as to his condition, and will—unless he be a man of unusual strength of mind—pitifully implore you to allow him an opiate to relieve his distress, declaring, if refused, that his life is in danger. At the same time he suffers much from pains in various parts of the body, but especially in the stomach and bowels; the pulse rises much in frequency—I have known it as high as 120; the tongue coated with white fur; there is unceasing thirst, and a total loss of appetite; the bowels, which were formerly confined, are now much relaxed, and a state of diarrhœa is established; the skin softens, and finally sweat pours from the surface."

Under these circumstances Dr. Flemming employs a combination of lupuline with phosphoric acid,—a nauseous dose, but comforting and soothing to the patient; lessening the force of his suffering, and making it tolerable in some cases within a week.

R Acidi phosphorici diluti, ʒx;
Tr. lupulinæ ad ʒxxx.—M.

S.—ʒii every four hours, one hour before food, in a wineglass of water.

With regard to diet, the patient is directed to have at first milk and beef-tea alternately every four hours until the appetite improves, when a stronger diet may be substituted. At night, if wakefulness is protracted, tinct. cannabis ℥xxx with spts. ether is employed with happy effects. In this way the patient and opium may be violently separated, but too often he yields again to its superior power before he can forget its blandishments. The will is too weak, the power of habit too strong.

So far as I am aware, no direct antidote to opium which is powerful enough for a case of this kind is known, but it has always appeared to me that there might be some *substitute* which by combination with other remedies, by a diminution of one and an increase of another, might *insensibly* supplant opium in the system. With this view I have made experiments with different drugs, with nostrums, and with proprietary medicines of several kinds. As the result of my experience, I venture to state finally with regard to some of the latter that the terms I have mentioned appear to be realized. If this is so, the fact is probably familiar to others, who ought to give an opinion on so important a subject.

CASE OF IDIOPATHIC TETANUS SUCCESSFULLY TREATED BY HYDRATE OF CHLORAL AND BROMIDE OF POTASSIUM.

BY W. S. MAXWELL, M.D.

EMMA W., aged four years and six months (colored), was taken on June 20, 1873, with griping pains in the epigastrium, intense thirst, occasional spasm, and some rigidity about the back. June 23, I was called in. She presented marked symptoms of tetanus: the jaws were partially closed and stiff, deglutition difficult, tongue dry, bowels constipated, trunk and extremities rigid, frequent spasms, breathing short, hurried, and anxious; no fever, pulse natural when quiet.

As to the history of the case, the mother told me that the child had eaten some berries in the woods the day before she was taken, and from her description I supposed them to be berries of the *Atropa belladonna*. The treatment commenced with a laxative, plenty of milk and whisky. Opium, cannabis Indica, quinine, and oil of turpentine were used, but to no purpose; the symptoms grew worse. On July 1 I ordered the following, stopping all other drugs:

Take of Hydrate of chloral,
Bromide of potassium, āā ʒiiss;
Water, ʒii.—Fluid solution.

Label.—Teaspoonful every three hours.

From the first there was marked improvement, and after continuing the remedy for a week the child was cured. She has enjoyed good health since.

STILL POND, MARYLAND.

IODOFORM ON VENEREAL ULCERS (*The Medical Record*, October 15, 1873).—Dr. G. O. Morrison-Fiset adds his testimony to the value of iodoform as a local application to venereal sores. He has found it of great use either in powder or suspended in glycerin.

TRANSLATIONS.

MYELOGENIC LEUCÆMIA.

DR. HUBER, in the *Deutsches Archiv für Klinische Medicin* for October, 1873, reports the following case of leucocythæmia:

The patient, a day-laborer, 43 years of age, came under treatment in October, 1870. His parents died advanced in years, and his only brother had good health. During the preceding eight years the patient had been subject to occasional chilly sensations of short duration, but there was nothing else to warrant the assumption of the existence of intermittent fever. For two years he had been complaining of loss of strength, cough, and dyspnœa. The skin was pale, temperature not increased, pulse regular, tongue clear, appetite and daily evacuations not affected. The lymphatics were not enlarged; legs were œdematous; no abnormal signs in chest; liver not enlarged; the spleen extended to crest of ilium and to the median line.

The urine was pale yellow, with a deposit of triple phosphates and urates. The proportion of red to white blood-corpuscles was ascertained to be two to one.

Death occurred the following January, ushered in by increasing dyspnœa, cough, and repeated epistaxis. The white blood-cells were very large, and some apparently contained yellow pigment-granules. In December he had an attack of pleurisy, with orthopnœa and cough. Urine was then still acid and full of urates. He had also a pustulous exanthem on the chest ten days before death.

The ribs, sternum, and sacrum were found to be full of dirty, greenish-yellow marrow. The spleen was twenty-five centimetres long and twelve centimetres broad, and was dense and resisting, with no attachments. The left pleural cavity was full of serous exudation. In the left ventricle of the heart were found a few drops of blood resembling pus.

Specimens were sent to Prof. Zenker, in Erlangen, who reported that under the microscope the splenic trabeculæ showed an unusually marked and symmetrical development. In the spaces, as in the splenic veins, were found fine spindle-shaped bodies sparsely distributed. These resembled those, unfortunately, still unknown crystals which have been frequently noticed as accompanying leucæmia, and which are by me considered as constant. The marrow of the ribs is strikingly soft and pulpy, is grayish red, and appears to be almost entirely composed of a multitude of medullary cells representing an uncertain transition stage between red and white blood-corpuscles. The crystals referred to existed in greater abundance in the bone-marrow than in the spleen or blood.

FRANK WOODBURY, M.D.

DISLOCATION OF THE SARTORIUS TENDON (*The Lancet*, November 8, 1873.—Mr. Hill reports the remarkable, and probably unique, case of a man, æt. 40, who, while squatting on the floor of a wagon, was fallen upon by a companion whose weight came on his bent knees. When he attempted to rise, the action caused him great pain on extending the leg, especially beyond a certain point. It was found that the sartorius tendon was dislocated backwards by the rupture of its anterior fasciculated expansion. The leg was first flexed until the swelling had subsided, and then put up in a straight back-splint with a foot-piece, a pad being placed over the tendon. At the end of a fortnight the limb was encased in a gum and chalk bandage, and a perfect cure was soon obtained.

RAPID DILATATION OF THE UTERINE ORIFICE (*British Medical Journal*).—Dr. Ellenger, of Stuttgart (*Archiv für Gynaekologie*, vol. v., fasc. 2, 1873), insists enthusiastically on the merits of rapid dilatation of the os and cervix uteri by his instrument. He considers that it ought to supersede sponge-tents, laminaria, and all other methods of slower dilatation. His instrument is based upon those of Perrève and Holt, used in rapid dilatation of the urethra; partaking, however, of the character of a speculum. The cases which he gives as especially suitable examples of success include examples of stricture of the cervical canal, stenoses associated with uterine flexions and deviations, menorrhagia due to softening of the parenchyma, to hypertrophy, or to uterine tumors, retention of disordered secretions in the cavity of the uterus. In one case, where the patient was suffering with hysteria and retroflexion of the uterus, forced dilatation cured a very obstinate neuralgia of the trifacial nerve.

VEHICLE FOR THE ADMINISTRATION OF CHLOROFORM.—A French medical journal remarks that the best course is to dissolve the chloroform in glycerin (1:3), which is effected with tolerable facility, and gives a very clear solution, pleasant to the taste, and with a strong odor of chloroform. This solution can be mixed in all proportions with water without the occurrence of any precipitation, though the odor is distinctly perceptible. In forming the mixture, it is well to add the chloroform slowly and to mingle the two thoroughly. It should be left at rest for twenty-four hours; at the expiration of this period a portion of the chloroform will be found to have collected at the bottom of the vase; this should be separated and mixed with an additional part of glycerin, when no further separation will occur. This mixture may be kept for some time without any loss of chloroform by evaporation.—*Boston Journal of Chemistry*.

NITRITE OF AMYL IN SPASMODIC ASTHMA AND ACUTE BRONCHITIS (*American Journal of Insanity*, October, 1873).—Dr. Daniel H. Kitchen has employed nitrite of amyl with great success in the paroxysmal cough and dyspnœa of acute bronchitis, and in the suffocative attacks of spasmodic asthma. He gives it, by inhalation, in doses of from six to fifteen drops, poured into a small cup-sponge and applied immediately to the nose, the mouth being kept shut. He believes its beneficial effect to be due partly to its sedative action on the muscular system through the motor nerves, and partly to its power of diminishing blood-pressure and causing contraction of the capillaries. He details four cases, in all of which a variety of other remedies had been unsuccessfully tried, and in all of which nitrite of amyl gave prompt and entire relief.

DIAGNOSIS OF SEX OF THE FŒTUS, IN UTERO (*The Medical Record*, December 1, 1873).—Dr. Willis E. Ford concludes from an analysis of eighty cases that no indication of the sex of the child can be obtained from the pulsations of the fetal heart, and also that the position of the latter during the last-month of utero-gestation is no guide to the presentation. In the majority of cases he found the sex of the child to follow that of the older and more robust parent.

DEATH FROM CHLOROFORM (*British Medical Journal*).—A death from chloroform occurred at Hamilton, in the practice of Dr. Dickinson, in the case of a man to whom the anæsthetic had been administered in order to facilitate the reduction of an old-standing dislocation of the shoulder-joint. The deceased had been a hard drinker. Dr. Dickinson used the venous injection of ammonia without any result. It is reported in the *Australian Medical Journal*, August, 1873.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

EDITORIAL.

THE LYMPHATIC SYSTEM.

TO us, one of the most curious results of recent anatomical investigations is the great extension which has been given to the prescribed boundaries of the lymphatic system. Not many years since, this system was believed to be a well-defined group of large glands and minute ducts; but advancing knowledge has demonstrated that the Peyer's patches of the intestines form a portion of the system; that the spleen in function and in structure is so closely allied to the lymphatics as to give it a place among them; that scattered through the parenchyma of such glands as the liver are minute microscopic cell-clusters, or, possibly, even single cells, whose anatomical structure and physiological functions entitle them to a position among the lymphatics. Very recently, Neumann and his coadjutors and successors have exalted the marrow of the bones into a similar rank, and Recklinghausen, widening still further the borders of this ubiquitous anatomical system by his researches with the nitrate of silver staining, has, seemingly, established that the serous membranes are great lymphatic sacs. His statements have been confirmed by Ludwig, Schweigger-Seidel, Dybkowsky, Dogiel, and Böhn; and, according to the London *Lancet*, Dr. Klein, now of London, has just completed an elaborate memoir upon the serous sacs, which is to form a portion of a great work on the lymphatic system. In this he confirms the views of

Recklinghausen. The following account of this memoir is taken from the number of the London *Lancet* for December 13:

"The chief points of novelty and interest in Dr. Klein's treatise, which is enriched by ten plates containing many beautiful and original drawings, are, first, that the endothelium of the free surface of the omentum, centrum tendineum of the diaphragm, and pleura mediastini does not everywhere present the well-known flat, tessellated character; but that in many places there are groups of polyhedral, club-shaped, and even short columnar cells, with granular contents, ovoid nucleus, and bright nucleolus. This peculiar form of epithelium Dr. Klein terms 'germinating epithelium,' because numbers of spheroidal cells may be seen in the act of separating or actually detached, which in all respects resemble lymph-corpuscles. The lymph-cells thus lying free in the interior of the great serous sacs make their way into the lymphatic system through small openings distributed over the membrane, bounded by peculiar cells, which instantly call to mind the *stomata* of plants, and to which the same name has been given. In the female frog many of the cells present the peculiarity of being ciliated, and they have been observed to perform amœboid movements. In the next place, Dr. Klein describes the cellular elements of the *matrix* of the serous membranes. These he represents as forming tracts, patches, or nodules by the accumulation of more or less flattened and branched cells, each lying in a cavity of the matrix but little larger than itself; the cavities communicate by passages, and contain, besides the above-named cells, lymph-corpuscles; the whole corresponding to Recklinghausen's lymph canalicular system. These, being outside the true lymphatic vessels, though in close relation with their walls, he terms perilymphangial nodules and tracts. In some parts a still higher grade of organization is reached, the cells developing within lymphatic vessels, and the matrix becoming a reticulum, and containing numerous lymphoid corpuscles, so as to form a kind of adenoid tissue, as Dr. Sanderson has elsewhere described. Finally, in the highest form or stage of development, the nodules become vascularized, the matrix consisting of a reticulum of large branched cells, the spaces of which are filled with fluid or a limited number of lymphoid corpuscles. Both the last forms of tissue he terms endolymphangial tracts or nodules.

"Thus it is seen that just as in hydrocephalus the structure of the brain is unravelled by the accumulation of fluid, so in the serous membrane we have a lymphatic gland opened out to our view. In one part the free surface is found to be covered with germinating cells, which develop into lymphoid or white blood-corpuscles; in another are structures—the perilymphangial nodules—closely resembling the cortical portion of the ordinary lymphatic glands; and in yet another, the endolymphangial tracts and nodules are vascularized structures identical with the medullary portion of the lymphatic glands. In all, the production of lymphoid

corpuscles takes place actively; and the whole may therefore be regarded as ministering to the production and development of blood."

WE desire to call attention to the circular published under the heading of *Notes and Queries*. No words of ours can add force to its statements; and we therefore content ourselves with warmly commending its object to our readers.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

IN the report of the Philadelphia County Medical Society in your issue of the 20th, the reporter quotes me incorrectly.

I not only saw smallpox in the "Neck," but also lost one case of the malignant type. In view of the surroundings, I was surprised at the paucity of cases occurring in that locality. So impressed was I by the probability of a rapid spread of the epidemic among these people, that I addressed a note to the Board of Health, urging their immediate attention to the disinfection of the contents of the wells before the conveyance of the "night-soil" to the truck farms.

In the hurry of my work I have been compelled to neglect my reading, and thus failed to notice this incorrect report.

Truly, etc.,

W. B. ATKINSON.

1400 PINE STREET, Dec. 27, 1873.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

DR. W. B. ATKINSON, PRESIDENT, in the chair.

A CONVERSATIONAL meeting was held at the hall of the College of Physicians, Wednesday, November 26, 1873, at 8 o'clock P.M.

A CASE OF EXTRA-UTERINE PREGNANCY—THE CHILD DELIVERED BY GASTROTOMY.

Dr. WASHINGTON L. ATLEE narrated the following interesting case: He had visited Mrs. O'D., of Linwood, Delaware County, in consultation with Dr. Cardeza, November 19, 1873. She was 28 years of age. Menstruation had commenced at the age of 17, and nothing unusual had occurred with regard to this function before marriage, except that during an attack of anæmia it was suspended for about three months. She was married January 12, 1871, and in the month of August following she had a miscarriage in the third month, caused by over-exertion. During this pregnancy she had no nausea or other trouble, and afterwards enjoyed her usual good health.

December 14, 1872, she menstruated for the last time. This was followed by the middle of January, 1873, with great irritability of stomach. The nausea and vomiting were troublesome until the sixth month, after which they diminished somewhat. She ate but little, and

became much reduced. The abdomen gradually became fuller, and she first felt motion in the early part of May, 1873, which subsequently became so well marked that her husband noticed it. The breasts increased in size, the nipples and follicles enlarged, the areolæ deepened in color, and milk could be pressed out. These signs of pregnancy became more and more developed until the third week of September, when Dr. Cardeza was called on to visit her, and found her suffering with pain resembling that of labor. Upon examination, however, he found the neck of the uterus not obliterated,—in fact, very little different from the natural condition. Believing that she had made a mistake in her calculation, he gave an anodyne and left her. Soon after, all fetal movements ceased. Dr. Cardeza was again called on a fortnight afterwards, and the patient was again apparently in labor, there being also a colored discharge from the vagina. The uterus presenting the same conditions as before, he suspected an extra-uterine pregnancy. The discharge referred to commenced October 1, was of a pale-red color, continued about three weeks, then ceased, and again returned for two days, after which it did not recur.

When Dr. Atlee saw her on the 19th of November she was in a state of great emaciation and prostration, with a pulse exceedingly feeble, frequent, and small; tongue red; the stomach rejected everything; the face was pallid, and the eyes were sunken; the body threw off a cadaveric odor; and all the symptoms indicated a state of profound septicæmia.

The abdomen was larger, much more prominent, and narrower than that usual in a woman at full term. It was elastic, and distinctly fluctuating. When pressed suddenly with the finger-points so as to displace the fluid, solid masses could be struck within, and these masses could be put in motion as if submerged in a fluid. The uterus was *in situ*; the os and cervix were patulous, and admitted the index-finger fully one and a half inches. The sound entered three and a half inches, and after having been introduced about two inches appeared to encounter a brittle substance, through which it seemed to tear its way. In front of the uterus a bulging elastic mass could be felt occupying the superior strait.

After making this examination, Dr. Atlee confirmed the diagnosis of Dr. Cardeza. In palpating the abdominal wall, Dr. Atlee noticed that the hypogastric region was much more dense than any other portion, and from this circumstance inferred that this was the point of attachment of the placenta.

In order to afford immediate and temporary relief, the patient was tapped through the linea alba, and seven pints of fetid, purulent fluid were removed; afterwards the form of a child, lying transversely, was readily traceable through the relaxed walls of the abdomen.

The family were advised of the extreme condition of the patient, and that the only hope of life depended on the removal of the dead child; and, under present circumstances, that chance was extremely remote.

The patient having survived a few days, Dr. Atlee was sent for again, and visited her November 24 for the purpose of performing gastrotomy. On entering the house he was met by the exclamation, "Doctor, I fear you are too late; she is dying." Her pulse was over 140, and very feeble; the eyes were staring, the pupils dilated, the abdomen was tympanitic, the mind dull, and she seemed almost *in articulo mortis*.

After stimulating her with brandy, and administering an anæsthetic, an incision about five inches in length was made in the linea alba from the umbilicus downwards through the thin walls of the abdomen, and directly into the cyst enclosing the child. So soon as the latter was opened, there was a rush of very offensive gas, followed by an escape of dirty fluid, containing

portions of dead matter, and also a loop of the umbilical cord. The child was lying crosswise,—the head towards the left side, with the abdomen forward. The feet were seized and the child extracted. It was a female, and was full grown. The placenta, which was attached to the abdominal wall in the hypogastric region, was peeled off by the fingers. It was pretty strongly attached. The sac enclosing the child was decomposed, and, as it protected the viscera from the air and constituted a cavity in itself, it was not disturbed. After cleansing it out with sponges wet with Monsel's solution, the cavity was loosely tamponed with ribbons of muslin moistened by the same solution, and the opening was closed by four sutures, allowing the ends of the tampon to escape from the lower end of the wound.

It was almost a bloodless operation. The section through the abdominal wall was not unlike an incision through the same parts of a body recently deceased, and the separation of the placenta was unaccompanied by bleeding.

Dr. ATLEE was assisted by Drs. Cardeza of Claymont, Drysdale and W. Lemuel Atlee of Philadelphia, and Forward of Chester.

The patient sustained the operation better than was anticipated. She did not lose strength; her pulse rose to 152, but was not more feeble; her voice was stronger, and her mind was clearer.

Dr. ATLEE remarked that the history of this case was peculiar, inasmuch as there were no hypogastric, colicky pains, and no sanguinolent discharge, during the first half of the period of gestation.

Dr. WELCH asked the doctor what anæsthetic was used.

Dr. ATLEE, in reply to Dr. Welch, said that he had used his usual mixture of two parts by weight of ether and one part of chloroform.

Dr. STETLER asked whether the physician in attendance was aware at nine months of her true condition.

Dr. ATLEE answered that when Dr. Cardeza was first summoned, on making an examination he found the cervix uteri intact, and supposed that the patient had made a mistake in her calculation.

Dr. ESHLEMAN asked Dr. Atlee what other attachments there were besides that of the placenta to the abdominal wall.

Dr. ATLEE answered that the membranes were attached to the surrounding parts, and constituted the cyst which enclosed the child. They were allowed to remain. This plan was adopted in a case on which Dr. Atlee successfully operated several years ago,—a patient of Dr. Hinkle. (See his book on the "Diagnosis of Ovarian Tumors," p. 194.)

Dr. HAMILTON thought the case of Dr. Atlee a remarkable one, in that the patient survived the operation; and inquired as to the amount of hemorrhage.

Dr. ATLEE remarked that there seemed to be a check to the capillary circulation, as there was no bleeding. He could understand how, in such a poisoned condition of the blood, passive hemorrhage might occur, or, should reaction come on, how bleeding might follow. For this reason he had used the styptic tampon to guard against it. He had employed Monsel's solution, both as a hæmostatic and an antiseptic.

Dr. KERR asked if there was any hemorrhage after the removal of the placenta.

Dr. ATLEE said there was none.

Dr. O'HARA inquired of Dr. Atlee if there had been a discharge or any symptoms whatever at the third month of pregnancy, and what was the diagnostic value of those symptoms.

Dr. ATLEE, in reply, said there was in this case no sanguinolent discharge in the earlier period of pregnancy. When it did occur, it was due to the separation

of the membrana decidua at that time. An intra-uterine decidua is formed in extra-uterine pregnancy. In this case the exfoliation and extrusion of the decidua had not occurred during the nine months of gestation, as proved by the examination with the sound, and hence there was no bloody discharge during that period.

Dr. WILLIAM GOODELL had seen a very analogous case, in which he made two humiliating errors of diagnosis. It occurred in the practice of Dr. W. C. Perkins, who published an account of it (*Philadelphia Medical Times*, March, 1872, p. 223, and *American Journal of Obstetrics*, vol. v. p. 155).

In this case Dr. Goodell wished to deliver the woman by an incision through the posterior wall of the vagina, but was overruled by her friends. He therefore tapped the womb through the vagina, and drew off clear undecomposed liquor amnii, with great relief to the patient. But she was at that time very low from acute anæmia, and died three days after. At the autopsy a fully-developed child was found within a very large central cyst. When an extra-uterine pregnancy goes to term, he believed it to be always ventral, and never tubal. In tubal pregnancy the cyst ruptures early, and the woman usually perishes from hemorrhage. Whatever the seat of an extra-uterine foetation, a decidua membrane invariably forms. If this is cast off whole, as in his case, the physician is very likely to mistake it for the product of an abortion, and thus lose his bearings. It was the presence of this membrane which had obstructed the passage of Dr. Atlee's sound. Whenever the womb is drawn up by its attachment to the growing cyst, and the cervix is consequently found high above the symphysis, the resemblance to a retroverted gravid womb is so striking that many excellent observers have been deceived. The great danger in a delivery by gastrotomy is hemorrhage from the placental site, for the blood-vessels are not there, as in the womb, constricted by muscular tissue. In view of this danger, recent writers have advised that in ventral foetation the placenta should be left to become spontaneously detached, and that in the tubal the whole cyst should be removed *en masse*.

Dr. O'HARA asked Dr. Atlee what would be the proper time to interfere, providing extra-uterine foetation was recognized, and what interference was necessary in the different varieties.

Dr. ATLEE replied that the rule is for tubal pregnancies to result in rupture before the expiration of the third month, and death occurs from hemorrhage into the peritoneal cavity. In ovarian and ovaro-tubal pregnancies such an occurrence is unusual, unless from violence or accident. In case of rupture of the cyst of either a tubal or an ovarian pregnancy, the abdomen should be opened without delay, and the cavity cleared of all foreign contents.

Dr. LEE asked Dr. Atlee whether he would wait until full term if a ventral pregnancy were previously discovered.

Dr. ATLEE said that unless circumstances called for the operation of gastrotomy before, he would regard the approach to the full period of pregnancy as the proper time to interfere, where both mother and child might be saved.

Dr. ESHLEMAN inquired of Dr. Atlee whether, in removing the placenta from the abdominal wall, he did not have to contend with profuse hemorrhage, as there could be no such contraction as occurs in the uterus to close the bleeding sinuses.

Dr. ATLEE remarked that in his case there was no hemorrhage from the placenta, but under different circumstances this was to be expected. In all cases of gastrotomy for the removal of an extra-uterine foetus, he would recommend, where there was trouble from

bleeding, compression of the abdominal aorta until the bleeding was controlled by appropriate styptics. The doctor said he had heard nothing from the patient up to this time.

He has since received a letter from Dr. Cardeza, saying that "she gradually sank from pyæmic poisoning forty-six hours after the operation."

Dr. ESHLEMAN related a case of *concealed hemorrhage* in connection with detached placenta at seven and a half months' gestation. The lady, from no assignable cause, suddenly felt a very distressing pressure across the pit of the stomach, and observed a corresponding swelling arise. Upon attempting to use the chamber, a gush of bloody serum half filled the vessel. He found the neck taken up, and was able to press his finger within the os and touch the head, which was pressing firmly against it. The womb felt thick and spongy, as in placenta prævia, so that the question arose at the time whether such could be the case and the placenta have been thrust aside by the child's head under the unremitting pressure. No excessive hemorrhage continued. The mother, who had given birth to several children, insisted that she had no pains. This constant pressure, aided, perhaps, by ergot, slowly opened the os, ruptured the membranes, and in twenty hours from the first symptoms pressed the dead fœtus from the mother. The case, thus carefully watched and left to nature, was attended with no very unusual hemorrhage.

The child, before labor very active, ceased to move after the first hemorrhage. It was pale and shrivelled. The cuticle detached with pressure. The placenta was removed from the uterus, and found covered on its maternal surface with firm, dark, coagulated blood, and was rather soft in texture. Its removal was in the course of thirty seconds followed by a firm, dark-colored clot of blood the size of a child's head. The mother made a good recovery.

Dr. GOODELL expressed the opinion that this case was one of concealed accidental hemorrhage. In other words, the placenta had become centrally detached, and blood had escaped into the cup-like cavity thus formed. Some years ago, his attention had been directed to this subject by the loss of a patient from this cause. He then collected and reported over one hundred examples of this very fatal accident (*American Journal of Obstetrics*, vol. ii. p. 281). The graphic description of Dr. Eshleman's, that the child did not appear to be delivered by labor-pains, but "to be pushed slowly out like forced-meat of a sausage-machine," was typical of this kind of hemorrhage. The acute distention of the womb by the effused blood prevented anything like true labor-pains, but it, notwithstanding, developed a very powerful *vis a tergo*. The remedy here was early rupture of the membranes and a rapid delivery by version or by the forceps.

Dr. H. LEAMAN then read a paper on "Accidental Hemorrhage during Pregnancy."

Dr. ESHLEMAN asked Dr. Leaman whether there was any evidence of concealed hemorrhage occasioned by the tampon, as there is some difference of opinion as to its use.

Dr. LEAMAN said there were no evidences of concealed hemorrhage; the bleeding ceased entirely under the use of the tampon, and the patient reacted with the help of stimulants.

Dr. GOODELL said, in the case of frank accidental hemorrhage narrated by Dr. Leaman, that, while appreciating the very embarrassing position in which the doctor was placed, a position which disarmed all criticism, he yet thought it would perhaps have been the better plan to perforate the membranes. The bleeding area would thus have been materially contracted, with a probable arrest of the hemorrhage. In case of failure,

the forceps or version could afterwards be resorted to. He then related the history of a case of post-partum hemorrhage from a lacerated cervix, in which he had finally to tampon with a sponge saturated with Monsel's solution. A strip of the cervix hung down like a ribbon, and the bleeding was so free that he did not dare to remove the tampon before the lapse of forty-eight hours. The decomposition of the retained clots set up a slight attack of septicæmia, but the patient did well upon their removal.

Dr. O'HARA asked if there was serious hemorrhage to be feared in a case of lacerated perineum. He had never seen much loss in these cases, but had heard of a case in which the practitioner was undecided whether it was from the womb or laceration.

Dr. GOODELL said that hemorrhage from a ruptured perineum was sometimes very profuse. He had, in fact, been present at a forceps-delivery in which firm packing of the wound with styptics was needed. The immediate closure of the rupture with silver-wire sutures would have been the proper treatment, but neither he nor the attending physician had their pocket-cases with them. With regard to secondary operations, he had not thus far failed to get an excellent union of the parts. In primary operations he could recall but one failure, and that in a craniotomy case, in which, after the delivery of the head upon very powerful traction, the sudden release of the shoulders tore the perineum quite down to the sphincter ani. On the third day puerperal mania set in, and the patient, by repeatedly jumping out of bed, and by struggling to throw herself out of the window, tore out all the stitches he had put in.

Dr. ESHLEMAN said he had seen profuse hemorrhage from a moderate rupture, but found it ceased when the sutures were applied.

Dr. WELCH related a case which he said possessed other interesting features besides that of hemorrhage occurring previous to delivery. The case was as follows. He was called some years since, in consultation with Dr. Hinkle, to visit Mrs. L., aged 40 years, in labor at the seventh month of gestation. She had been pregnant seventeen times. Eleven children were born at term, and six miscarried. The patient was found suffering from uterine hemorrhage, which had continued for one month. The hemorrhage was not sudden, or gush-like, but of a slow, continual, draining character, which had reduced the patient to a pallid, feeble condition. By examination, Dr. Hinkle found the os tolerably well dilated, and the face of the child presenting, with the chin towards the symphysis. This presentation was readily converted into an occipital, and the forceps were applied; but on making traction they slipped off. It was then learned by digital examination that the child had been dead for a considerable length of time, and that decomposition had taken place to such an extent that the cranial bones had given way at their sutures under the pressure of the forceps. The decomposition was so marked that Dr. Welch was able to perform craniotomy with his index-finger; and, after extracting as many of the bones as possible, he succeeded in delivering the child by winding the scalp around his fingers, with little or no assistance by uterine contraction, although ergot had been freely administered. The placenta, which was found detached, was immediately delivered, but no contraction of the uterus followed. The blood continued to flow, now more profusely than before, and the patient by this time was without any perceptible pulse at the wrist, and was almost reduced to an exsanguineous state. Indeed, so feeble was she that she could only utter monosyllables in a whispering tone. Finding that ergot had failed to act, ice was next used: a small piece was carried well up into the cavity of the uterus, which also failed to produce contraction. Observing that the patient appeared un-

conscious of the presence of the ice in the cavity of the uterus, the question was asked, "Do you feel that?" She replied, with surprise, in a whispering tone, "Feel what?" It was evident that the ice was doing no good, and that it should no longer be relied upon. Vinegar was next used, and with a very decided result; for when the rag saturated with vinegar had just barely reached the cavity of the uterus, the patient shrieked with pain, the uterus contracted violently, the hemorrhage ceased, and a speedy recovery followed. The cause of the accidental hemorrhage was doubtless due to a partial detachment of the placenta, which the patient accounted for by a slight fall on the stairs a few days before the appearance of the bloody discharge. The most interesting feature in this case is not the accidental hemorrhage occurring before delivery, but the prompt and speedy arrest of the post-partum hemorrhage by the use of vinegar.

GLEANINGS FROM OUR EXCHANGES.

INCONTINENCE OF URINE AFTER LABOR (*British Medical Journal*, December 6, 1873).—Mr. Golding Bird reports the case of a woman, aged 32, who suffered from incontinence of urine as the result of a tedious and prolonged labor, in which forceps were applied. The escape of urine was constant; she was mentally depressed, and experienced much pain. The absence of any vaginal fistula was proved by injecting the bladder with colored water, none of which returned by the vagina. On examination per vaginam, there was found plastic effusion around the urethra, the base of the bladder, and lower part of the uterus, fixing the parts completely, so that the sphincter vesicæ was prevented from closing. The bladder was very irritable, much contracted, and could only contain an ounce of urine, and that with much distress. This condition was treated by injecting the viscus with one to two grains of morphia in about half an ounce of water, the operation being preceded by a slightly forcible injection of water to increase mechanically the capacity of the organ. After this was done, the water was allowed to flow, and the morphia, being injected, was retained as long as possible. The quantity used for distention depended on the distress produced: it was never carried beyond slight pain. By these means the bladder was enabled to hold first two, then three ounces; and, as the cellulosic deposit became absorbed and the power of the sphincter increased, she was able to hold fluid better, until in about three weeks she could voluntarily retain her urine for half an hour.

The thickening gradually passed off, and in six weeks—when she passed from under observation—the bladder could hold eight ounces.

ATROPIA IN PHTHISICAL SWEATING (*British Medical Journal*, November 29, 1873).—A notice in the *Philadelphia Medical Times* of last year, in which Dr. J. C. Wilson stated that he had successfully used sulphate of atropia in doses of one-eightieth of a grain for the relief of profuse sweating in four cases of phthisis, led Dr. Fräntzel to make an extended series of researches in the Charité Hospital in Berlin on the effect of atropia in such cases. In a paper on the subject published in *Virchow's Archiv*, vol. lxxviii. part i. (*Allgemeine Medicin. Central-Zeitung*, August 2), he states that, having given it to seventy-five cases, he has arrived at the conclusion that it is a remedy that he can confidently recommend not only in phthisical sweating, but also in that which attends other diseased conditions, such as acute articular rheumatism and convalescence from trichinosis. Among the seventy-five cases were fifteen

cases of more or less recent cheesy pneumonia, of whom all had more or less fever with night-sweats; forty-eight of distinct pulmonary phthisis, of whom forty-two had hectic; one of acute articular rheumatism with high fever; two of ulcerative endocarditis, and two of trichinosis. In the first fifteen patients the sweating was in six completely arrested, in seven much diminished, in two there was no change. In the forty-eight phthisical cases, the medicine had no effect in five, in twenty-one the sweating was remarkably abated, and in twenty-two it disappeared entirely. Several of the patients in whom the atropia failed were near death when it was given. In the eight cases of rheumatism the atropia gave permanent relief in five, in two it produced a marked diminution of the sweats, in one it was useless. In one of the cases of ulcerative endocarditis it proved useful; not so in the other. In the two cases of trichinosis the cessation of the acute stage of the disease, and of the hectic fever attending it, was followed without any rise of temperature by profuse night-sweats. Sulphate of atropia, in doses of a milligramme (.015 grain), was given two hours before the expected access of sweating daily for five days in succession in one case, and for three days in the other; the result being that the sweats entirely disappeared from the first evening when it was given. In one of the cases of rheumatism, in a man aged thirty-two, nearly all the large joints of the upper and lower limbs had been severely affected during five days; the patient was covered with sudamina, and, when seen by Dr. Fräntzel, was bathed in sweat. A milligramme of sulphate of atropia was given immediately, and very soon there was an abatement of the sweating, which in two hours disappeared. It returned in the night, but ceased the next forenoon after the administration of a similar dose. The atropia was thenceforth given regularly night and morning, with the effect of completely preventing the sweating. The fever lasted fourteen days. In another case of acute articular rheumatism, atropia was given first in doses of one, then of two milligrammes, with a similar result; and it is remarked that on two days in the course of the disease in which it was omitted, the sweating recurred. The atropia was given according to the following formula: sulphate of atropia, six milligrammes (9-100ths of a grain); extract of gentian, sufficient to make ten pills. Dr. Fräntzel has never given larger doses than 1.2 milligrammes (a little less than one-fiftieth of a grain), from fear of producing toxic symptoms. Even doses of 0.6 and 1.2 milligrammes, though unattended with any mischief, have produced slight symptoms of poisoning. In not a few cases after taking the medicine, the patient felt itching in the neck, which, however, disappeared in one or two hours. The pupils not unfrequently acted slowly, and were sometimes dilated. In some cases there were muscæ volitantes. The atropia had to be stopped in four cases on account of diarrhœa: that this was due to the medicine was proved by the fact that it ceased when the atropia was discontinued, and reappeared when it was resumed. What the physiological action of atropia is in arresting perspiration, Dr. Fräntzel says it is difficult to determine. He is, however, inclined to believe that the profuse sweats arise from relaxation of the walls of the vessels supplied to the sudoriferous glands; and he remarks that the researches of Meuriot, Fleming, Jones, Hayden, and Brown-Séquard have shown that atropia contracts the smallest vessels. To this are to be ascribed both the diminution of the sweats and the dryness of the mouth and skin observed in cases of poisoning with belladonna and with atropia.

SUPPRESSION OF URINE (*British Medical Journal*, November 22, 1873).—Mr. Albert Kisch reports the case of a female, æt. 47, who, when he first saw her, had not

passed urine for eleven days. There was nothing in her countenance or general aspect to arrest attention, but the tongue was exceedingly anæmic and slightly coated at the back, and there was a continual sense of nausea. She had vomited once on the preceding day. She had been subject to diarrhœa for some years, and to continual drowsiness, which often passed into sleep with heavy snoring; she had frequently suffered from aching in the back; the urine, which was never very copious, had been somewhat reduced for two months, and there had been some puffiness about the lower eyelids.

A catheter was passed, but not a drop of urine escaped. The bowels having been freely relieved by saline cathartics, she was then treated by dry cupping in the loins, fomentations of digitalis over the abdomen, and infusion of digitalis internally. She was placed on a diet of water and skimmed milk, *ad libitum*, with a little bread and beef-tea.

About noon on the following day she passed three drachms of very turbid urine, albuminous, crowded with blood-disks and epithelial cells from the genito-urinary tract, and exhibiting a few epithelial casts. Two hours later she passed urine freely; it was pale, clear, feebly albuminous, with a few casts, but free from blood-disks. Early in the next day she had a severe convulsive seizure, which was succeeded by others with varying frequency until her death, which occurred two days later. The case is interesting from the long and almost absolute suppression of urine without anasarca or other prominent symptoms, and from the occurrence of convulsions subsequent to the free passage of urine. The latter must have been the product of the excreting and not the secreting part of the kidneys, and was clearly nothing more than the *urina potius*, due to the copious liquid diet. No necropsy was permitted, but the kidneys were probably small and granular, and diseased to such a degree that the whole of the cortical and the greater part of the medullary portion had ceased to act.

HYPODERMIC INJECTIONS IN THE TREATMENT OF CHOLERA (*Indian Medical Gazette*, November 1, 1873).—Surgeon A. R. Hall believes that in the collapse of cholera the patient is not suffering from nervous exhaustion, but is being *suffocated* by spasmodic contraction of the muscular coats of the arteries, due to the same cause as the vomiting and purging,—a specific irritation of the medulla oblongata and sympathetic nerve. Proceeding on this theory, he has treated his last case of cholera by subcutaneous injections of chloral hydrate, which he asserts to be one of the most powerful cardiac sedatives we possess. The patient when first seen was in a state of collapse, had the regular choleraic voice, fingers blue and wrinkled, and pulse barely perceptible at the wrist, although the heart was beating strongly; there were frequent vomiting and purging, cold skin and breath, shrunken eyes, and cramps in the legs; he had not passed urine for several hours. One scruple of chloral was given by the mouth, but was immediately rejected. Five grains of chloral in solution in fifty minims of water were then injected under the skin of the arm. His hands and feet soon became warmer, and his radial pulse more perceptible. In about two hours vomiting and purging increased, and his hands grew colder; two and a half grains additional were injected, and two hours later the same quantity again. In a short time the vomiting subsided, the temperature rose, and he passed a small quantity of highly albuminous urine. He steadily improved, was well fed for a few days, and made a rapid recovery. Three other cases treated similarly by another practitioner all resulted equally favorably.

A correspondent of *Le Progrès Médical*, November 22, advocates the hypodermic injection of sulphuric ether and other stimulants in adynamic cases, and

mentions one in which the injection of from two to three grammes of pure ether was the means of bringing a patient through the algid stage of cholera after all other remedies had failed.

THE DETECTION OF STONE (*British Medical Journal*, December 6).—At a recent meeting of surgeons at the Medical Society, Mr. W. D. Napier described his instruments for the detection and removal of stone in the bladder. The diagnostic properties of the sound or "detector" invented by this gentleman depend on its beak being coated with lead, and on the soft and polished surface thus obtained becoming scratched by the slightest contact with any hard substance. If the calculus be small, or if fragments remain after crushing operations, recourse must now be had to the second instrument, which consists of an india-rubber tube, with expanded extremity, not unlike an ordinary convolvulus. Introduced in a folded condition through a species of catheter tipped with cacao-butter, the removal of the canula permits the full opening-out of the cup, which acts as a species of wing in retaining the instrument towards the neck of the bladder. The force of gravitation now inclines any foreign body to be drawn within the pliable and elastic walls, and the process of removal may be completed without any fear of injury to the mucous membrane from the sharp edges of fragments. Mr. Napier concluded by an interesting demonstration on a prepared bladder and urethra, and an animated discussion ensued, in which most of the surgeons present took part.

RUPTURE OF THE STOMACH (*British Medical Journal*, November 22, 1873).—Mr. H. Kirwan King was summoned hurriedly to his office, and found a man staggering about, unable to speak, but groaning with acute pain, and both hands pressed firmly into his stomach. He fell down in a state of collapse, and died in a few minutes.

At the post-mortem examination, two enormous clots were found on each side of the spine; and on the anterior surface of the pyloric pouch was an irregular aperture with edges infiltrated with black blood, and presenting appearances of ulceration. The upper portion of the duodenum was distended with clots. The liver was quite healthy; but a roundish gall-stone, about the size of a nut, was firmly impacted in the neck of the gall-bladder. The remaining viscera were quite healthy. The rupture was probably induced by the efforts made to relieve the pain of the gall-stone by violent pressure to the epigastrium; the coats of the stomach, being preternaturally weakened by ulceration, gave way, and the patient died from the shock.

ERGOT IN EPISTAXIS (*The Medical Record*, October 15, 1873).—Dr. Andrew H. Smith reports the case of a man, æt. 37, who suffered from persistent epistaxis, recurring sometimes two or three times a day. Direct and rhinoscopic examination showed no abnormal condition of the nasal mucous membrane. Astringents were applied locally by means of both the brush and syringe, and such general treatment was resorted to as the symptoms demanded. After this had been persevered in for two weeks without affecting the hemorrhages, the fluid extract of ergot was prescribed in twenty-drop doses three times a day.

This was continued for ten days, with the effect of entirely restraining the bleeding from the time the first dose was taken. The medicine was then omitted, but in a few days the bleeding began anew. It was immediately arrested by a resort to the drug, and did not afterwards return; the medicine being continued at gradually-increasing intervals for nearly a month.

INOCULATION OF SYPHILIS IN CIRCUMCISION (*New York Medical Journal*, December, 1873).—Dr. R. W.

Taylor, of New York, in an interesting communication "On the Question of the Transmission of Syphilitic Contagion in the Rite of Circumcision," considers this subject—which is one of importance to the Jews of our population—in a most thorough manner. Four cases of suspected syphilis, supposed to have been acquired in this way, are carefully analyzed, and the results presented.

The conclusions which Dr. Taylor arrives at upon this subject may be summed up briefly as follows: That in the Jewish rite of circumcision there is a possibility of syphilis being acquired; that the contagion is most likely to occur in the act of sucking the wound. Dr. Taylor recommends that the operation of sucking should be wholly abolished, and if a styptic solution of any kind is used it should be poured from a vessel on the wound rather than squirted upon it from the mouth of the operator.

MISCELLANY.

DISEASE-DESTROYING TREE.—M. Gimbert, who has been long engaged in collecting evidence concerning the Australian tree *Eucalyptus globulus*, the growth of which is surprisingly rapid, attaining besides gigantic dimensions, has addressed an interesting communication to the Academy of Sciences. This plant, it now appears, possesses an extraordinary power of destroying miasmatic influence in fever-stricken districts. It has the singular property of absorbing ten times its weight of water from the soil, and of emitting antiseptic camphorous effluvia. When sown in marshy ground it will dry it up in a very short time. The English were the first to try it at the Cape, and within two or three years they completely changed the climatic condition of the unhealthy parts of the colony. A few years later its plantation was undertaken on a large scale in various parts of Algeria. At Pardock, twenty miles from Algiers, a farm situated on the banks of the Hamyze was noted for its extremely pestilential air. In the spring of 1867 about thirteen thousand of the eucalyptus were planted there. In July of the same year—the time when the fever season used to set in—not a single case occurred; yet the trees were not more than nine feet high. Since then complete immunity from fever has been maintained. In the neighborhood of Constantine the farm of Ben Machydlin was equally in bad repute. It was covered with marshes both in winter and in summer. In five years the whole ground was dried up by fourteen thousand of these trees, and farmers and children enjoy excellent health. At the factory of the Gue de Constantine, in three years a plantation of eucalyptus has transformed twelve acres of marshy soil into a magnificent park, whence fever has completely disappeared. In the island of Cuba this and all other paludal diseases are fast disappearing from all the unhealthy districts where this tree has been introduced. A station-house at one of the ends of a railway-viaduct in the Department of the Var was so pestilential that the officials could not be kept there longer than a year. Forty of these trees were planted, and it is now as healthy as any other place on the line. We have no information as to whether this beneficent

tree will grow in other than hot climates. We hope that experiments will be made to determine this point. It would be a good thing to introduce it on the West Coast of Africa.—*Times and Gazette*, Nov. 1, 1873.

A MAN advertises for a competent person to undertake the sale of a new patent medicine, and adds that "it will prove highly lucrative to the undertaker."

NOTES AND QUERIES.

TO THE MEDICAL PROFESSION AT LARGE.

IN obedience to the resolution of the Convention of Physicians, lately assembled in this city, we undertake this address to your sympathy, with full assurance that its hallowed object will secure your cordial support.

But yesterday our community was as a house of mourning, and its wail of distress, arising from stricken hearts and desolate homes, smote the ear of the world with the horrors of our affliction. Those of our people who remained in the doomed city can only appreciate the sad story of suffering seen and felt in our midst, when death thus held, for seven long weeks, its high carnival among us. Over the entire city death and silence brooded. Its deserted streets, alike both day and night, scarce echoed a sound save the mournful horse-rattle as it hurried to the grave its load of dead, or the footfalls of those ministers of mercy who lighted up the hours of darkness with their visits of charity. Silently and continually the pious labor of love was performed, and each rivalled the other in the patient discharge of a common humanity. When the shaft of death prostrated one, another with true Corsican spirit took his place, and the work of benevolence went fearlessly on, until under the favor of Heaven the disease was baffled and the reign of terror at an end. Each creed, sect, order, and brotherhood had its heroes and its martyrs, and it is in commemoration of the deeds of both the living and the dead that our hearts should never suffer forgetfulness.

The faithful physician who survived the storm bears in his conscience its plaudits of duty done; but our seven brothers, Williams, Freeman, Crone, Hatch, Kennon, Blount, and Minor, fallen at their post, martyrs to the cause of humanity, ay, bright exemplars of professional honor and duty, sleep in their quiet graves, with more lasting glory than embalmed warriors in piles of storied marble. Our fallen brothers, if they could be consulted, would doubtless wish no fitter burial than quiet interment in leafy Elmwood, but professional pride demands the honor of their perpetual commemoration, and we ask in this behalf that suitable stone be raised and carved for them. Their fame, the story of their heroism, belongs to the medical world, and our brethren throughout the broad land are respectfully requested to contribute something to this laudable end. Your contributions, however small, will aggregate a success of the enterprise.

Remittances may be made to either member of the Committee.

RICHARD H. TAYLOR, M.D., 44 North Court Street.

F. L. SIM, M.D., 115½ Beale Street.

R. W. MITCHELL, M.D., 275 Main Street.

MEMPHIS, TENN., November 10, 1873.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Dr. J. Solis Cohen will read a paper before the Society, Wednesday, January 14, at 8 o'clock P.M., on "Croup in its Relations to Tracheotomy." All regular practitioners of medicine in the city are invited.

THE letter from "Fizzie" has been received. The editor of the *Philadelphia Medical Times* is always obliged for any hints or suggestions as to the management of the journal, but would certainly be more affected by the advice if the author had had the backbone to sign his name.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 30, 1873, TO JANUARY 5, 1874, INCLUSIVE.

ABADIE, J. H., SURGEON.—Granted leave of absence for four months, on Surgeon's Certificate of Disability. S. O. 1, A.G.O., January 2, 1874.

SATURDAY, JANUARY 17, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON TWO CASES IN WHICH CEREBRAL SYMPTOMS WERE PRODUCED BY THE USE OF WHITE LEAD AS A COSMETIC.

Delivered December 17, 1873,

BY JAMES H. HUTCHINSON, M.D.,

One of the Attending Physicians to the Pennsylvania Hospital.

AT my last clinic I brought before you a patient who had been poisoned by using white lead as a cosmetic, and referred briefly to another patient in my wards in whom I believed certain symptoms, at that time of little severity, were due to the same cause. The latter has since died, presenting, before her death, well-marked cerebral symptoms; and I propose, therefore, to occupy a part of the hour this morning with some remarks on the graver forms of lead-poisoning, so well illustrated by these two cases.

Case I.—E. R., æt. 21, born in England, single, and of irregular habits, was admitted into the women's medical ward of the Pennsylvania Hospital, November 18, 1873. The following history was obtained from the patient shortly after her admission. The patient is free from any known hereditary taint. Her mother is subject to attacks of hæmoptysis, but her father and several brothers and sisters are in good health. She states that when sixteen years of age she contracted a chancre, which was followed in due time by a cutaneous eruption, probably roseola, by sore throat, and by ulcers on the outer and lower third of both thighs and in both popliteal spaces. She was laid up with these for eighteen months, and during that period suffered from amenorrhœa and profound anæmia. During last winter she had an attack of subacute rheumatism, accompanied by swelling of the joints, and last summer was taken with spitting of blood, for which she was admitted into the hospital by my colleague Dr. John F. Meigs. She appears to have been at that time anæmic, and to have suffered from dysmenorrhœa and obstinate constipation, but during her stay here had no hemorrhage from the lungs. She tells us that her bowels are often not moved for several days in succession, and that she occasionally has colicky pains in the abdomen. It is found, on questioning her, that she has been in the habit of applying a powder to her face as a cosmetic. For some time past she has been an almost constant sufferer from frontal headache. Three or four weeks ago she observed that her eyes were drawn inwardly, and that her eyesight was growing dim. She has had marked dizziness and double vision. She has never had a convulsion, and has never lost consciousness.

On admission, the patient is extremely weak, very anæmic, and when she talks or moves hand or foot muscular tremblings are observed. The right pupil is larger than the left, the latter being about normal in size. There is marked dimness of vision, and internal strabismus on both sides; there is no paralysis of any other of the muscles of the eye than the external rectus,

and none of any of the muscles of the face. The grip of the left hand is feebler than that of the right, and she thinks that there is some loss of power in the left leg, although this is not very evident. Sensation is unimpaired. She complains of pain in the forehead and in the vertex, and occasionally in the lower occipital region. A well-marked blue line is seen on the gums just above the insertion of the teeth. The tongue is pale, the appetite poor, the stomach occasionally irritable, and the bowels continue costive; the chest is healthy; the menses are regular. When the patient rises or turns in bed she becomes giddy, and in consequence she is unable to stand without assistance. The veins of the forehead are turgid with blood. An ophthalmoscopic examination shows the existence of marked optic neuritis in both eyes. The urine is acid and is loaded with urates, but contains no lead, no sugar, and no albumen. It has a specific gravity of 1020. She was ordered ten grains of the iodide of potassium three times daily.

A little of the powder which she had been in the habit of applying to her face was obtained from her and analyzed by Mr. Hecker, the apothecary of the hospital, who found it to be pure white lead.

November 28.—The patient had an attack of vomiting last night, during which she threw up a large quantity of a greenish liquid. This morning she is pale and much prostrated; there is general muscular soreness and slight fever, and some pain in the hepatic region. Pulse 100. R Potassæ citratis, gr. x; Tr. opii deodoratæ, gtt. iii, q. t. h. The iodide of potassium to be suspended for the present.

November 29.—Better again.

November 30.—Slightly delirious last night. The frontal headache persists, but is not so intense as formerly. The fever-mixture ordered on the 28th to be stopped; the iodide to be renewed.

December 1.—Delusions and emotional disturbances to-day: for instance, the patient asserts that she was forced to sleep in the stable last night. A sixteenth of a grain of the bichloride of mercury was added to each dose of the iodide.

December 3.—Is much better to-day, and is able to be out of bed and to walk a little.

December 8.—The improvement noted on the 3d continues. The muscular tremblings are less decided. The frontal headache is less severe, and now only troublesome at night. The dizziness has almost entirely disappeared, and the squint, although still present, is scarcely noticeable. Temperature, A.M., 97½°; P.M., 98°.

December 9.—Temperature, A.M., 97°; P.M., 98°. Basham's mixture, in tablespoonful doses, to be repeated every three hours, was ordered to-day. She has been taking six grains of quinia daily since the 6th.

An ophthalmoscopic examination showed the continuance of optic neuritis, the inflammation involving a narrow zone of the retina immediately surrounding the disk. In the right eye the remainder of the retina was quite healthy. In the left eye the inflammatory changes had extended towards, and to a slight extent involved, the macula. A number of small, brightly reflecting spots were seen arranged in rows, producing an appearance which has been compared by Soelberg Wells to that presented by a cluster of spider's eggs.

Case II.—M. C., æt. 23, native of Ireland, a copyist by occupation, was admitted into the women's medical ward of the Pennsylvania Hospital, December 2, 1873. The patient is of healthy parentage, and states that she has herself always had good health until two months ago, when she began to suffer from headache, general weakness, and loss of appetite. She did not, however, take to her bed until two weeks before her admission,

*The notes of this and the following case were taken by my clinical clerk, Dr. George S. Gerhard.

when she was seized with violent gastric pain, nausea, and vomiting, her bowels being confined. She continued to suffer from such attacks until she sought relief in the hospital.

On admission, the patient presents a very anæmic appearance. The conjunctivæ are slightly yellowish, her tongue is furred, and her bowels are constipated, although not obstinately so. There is a faint but well-defined blue line on the gums, and it is found, on questioning her, that she has been in the habit for years past of applying a cosmetic powder to her face. A box of powder which she has with her is found on examination to be composed of inert substances, but she says that she has not always bought the same powder, and she may, therefore, have occasionally used one containing lead. There is a good deal of general muscular soreness, but no evidence of loss of power in any part of the body. The urine is acid, has a specific gravity of 1020, and contains neither albumen nor any other abnormal constituents.

December 3.—The patient had a violent paroxysm of gastric pain last night, accompanied by nausea and vomiting. She was ordered ten grains of iodide of potassium three times a day.

December 6.—In spite of the patient's denial that she had ever used lead knowingly, we find through one of her friends that she has been in the habit, for some time past, of mixing white lead with water and applying it to her neck and shoulders.

December 9.—There is some improvement in her condition to-day; the vomiting taking place generally only early in the morning, immediately after rising, and very rarely after eating. She has little or no pain at present in the region of the stomach. She complains, however, of pain in the inter-scapular region, and along the course of the musculo-spiral and radial nerves of both sides. There is no tendency to wrist-drop, and none to colic. The bowels are moved daily.

December 11.—The patient is to take, hereafter, five grains of citrate of iron with each dose of the potassium. She has very much improved in appearance; the conjunctivæ are less yellow.

December 13.—An epileptiform convulsion occurred last night at 10.15 o'clock, lasting, it is said, about five minutes, but it was not timed by the clock. During this convulsion the patient foamed at the mouth and moved both her hands and her feet, but one side was more convulsed than the other. She had a second convulsion half an hour later, a third at 3 A.M., and a fourth at 7 A.M., all of them being of the same character as the first, and lasting about the same length of time. She was apparently unconscious both during and for a short time after the attacks. This morning she is very restless, and is constantly crying out. She is entirely free from fever and flushing of the face. Her pulse is 98. Her pupils are of equal size, somewhat dilated, but contract under a bright light. Her tongue is moist. A turpentine injection was ordered, and cold affusion to the head. The iodide of potassium to be continued.

December 14.—Another convulsion occurred yesterday afternoon at 2 o'clock, since which time the patient has been so restless and so noisy that it was necessary to tie her in bed and to place her in a room by herself. This morning she has some heat of skin, and a dry and somewhat brownish tongue. Her pulse is 80. The right pupil is larger than the left. Neither pupil responds very promptly to the light. She frequently cries out, and complains of pain at the nape of the neck, which is slightly rigid. The head is somewhat retracted. She is able to swallow milk and beef-tea, which have been freely administered to her since yesterday, and have been retained. The bowels were moved yesterday by the turpentine injection. A hypodermic injection of a twelfth of a grain of sulphate of morphia

last night, followed by a two-grain opium suppository, failed to induce sleep.

An ophthalmoscopic examination of the right eye, made by Dr. W. F. Norris, shows the presence of optic neuritis in a marked degree. The patient's sister, who was seen to-day, states that she (the patient) has never complained of dimness of vision or of vertigo, and, excepting queer muscular movements when she was excited, and infrequent attacks of headache during the last half-year, she always appeared to be quite well until the beginning of the troubles for which she was admitted. The sister has a specimen of the preparation which the patient has been applying to her neck and face, but says it is useless to examine it, for it was bought for white lead and was so marked by the apothecary who sold it.

December 15.—The patient had a convulsion at 7 o'clock last evening, and another three hours later, during which she died.

It is said that while in the last two convulsions she moved her arms freely, but her lower extremities appeared to be paralyzed.

Autopsy, thirteen hours after death. The body was well nourished. Rigor mortis pronounced. Hypostatic congestion of dependent portions of the body unusually well marked. The calvarium was rather thick, but free from any disease. The veins and sinuses of the dura mater were turgid with a very fluid and dark-colored blood. The cerebral membranes were perfectly healthy. The brain, which was carefully examined at my request by my colleague Dr. Hunt, was exceedingly anæmic, the gray matter presenting rather a yellowish appearance, but there was no evidence of disease of any kind. The spinal veins were also engorged, and there was a marked increase in the amount of spinal fluid. The thoracic and abdominal viscera were all examined and found to be congested, but otherwise were in a normal condition, except the ovaries, in which cystic degeneration had commenced.

The posterior part of both the eyeballs was removed and sent to Dr. Norris for minute examination. Some prominence of the optic disks could be detected by the unassisted eye.

Since the autopsy, the following hurried note has been received from Dr. Norris with reference to his ophthalmoscopic examination: "The right eye of M. C. was very similar in appearance to that figured by Mr. J. Hutchinson (see *Ophthalmic Hospital Reports*, February, 1871) in Fig. 1: viz., outlines hazy; color bluish white and opaque; sclerotic ring not visible; vessels very much diminished in calibre; no choroid changes."

I will now read the notes of a third case, in which the symptoms of lead-poisoning are less severe, but in which it has been caused in the same way.

Case III.—M. K., æt. 18, born in America, an umbrella-maker by occupation, was admitted into the medical ward of the Pennsylvania Hospital, October 7, 1873. She is free from any hereditary taint, and until the beginning of her present trouble always had good health. About four weeks before admission she observed that her hands trembled when raised, and soon afterwards that she was unable to extend them fully. She states that for six months previous to the appearance of these symptoms she had been in the habit of applying a preparation to her face as a cosmetic, "to take the shine off the skin," which, upon examination, was found to consist mainly of carbonate of lead. She has not suffered from colic, but her bowels have been at times constipated.

On admission, the patient has well-marked wrist-drop,

especially on the right side, and the characteristic blue line of lead-poisoning is observed on the margins of the gums. The extensor muscles of the forearm respond feebly to the faradaic and galvanic currents. The deltoid and biceps of the right side are weaker than the corresponding muscles of the left side. She is anæmic and weak. Her appetite is poor. Her bowels are regularly moved. The urine is normal, and does not contain lead. She was ordered ten grains of iodide of potassium, and a mixture composed of gentian and iron, three times daily, together with galvanization of the affected muscles.

November 1.—Patient improving. Has now slight control over the extensors of the wrist.

November 24.—The extensors continue to grow stronger. The muscles have been faradized daily for some time past, and contract better than they did. The blue line on the gums is now very indistinct.

November 27.—Although the wrist-drop, especially on the right side, is not yet overcome, the patient is now able to use the right hand in writing. Her general condition has also very much improved. In addition to the internal use of iodide of potassium, the fortieth of a grain of sulphate of strychnia is now injected daily over the muscles of the forearm.

I have nothing to say this morning in reference to the third case; the patient has already been before you and formed the subject of a clinical lecture by my colleague Dr. J. F. Meigs, and I would not have brought her down again into the amphitheatre were it not that the lead-poisoning was produced in the three cases in precisely the same way,—*i.e.*, by the use of white lead as a cosmetic. In every instance it had been used for some time before it produced any bad effects,—in the case of E. R. for two years. It is possible, of course, that until very recently it was not absorbed by the skin; it is more probable, I think, that she has been poisoning herself by a slow process, until thorough saturation of the system has at last taken place. Cerebral symptoms, if I may judge from the writings of English and American physicians, are not very frequently met with as the consequence of lead-poisoning either in this country or in Great Britain; they seem to occur with great frequency in France and Germany. Before the two cases the history of which I have just read came under my observation, I had seen but one other case, which was only a short time under my care before it ended fatally, and of which I have preserved no notes. I remember, however, that the patient had epileptic convulsions, and that he was violently delirious; in fact, his delirium was so violent that he had to be restrained. At the time he was under my care the ophthalmoscope was not in general use as an aid in the diagnosis of cerebral disease, and the condition of his eyes was of course not noted either before or after death.

The diagnosis of the first of my cases presented some points of difficulty. The distinct history which we were able to obtain of a syphilitic infection, and of the secondaries which followed this infection, led me at first to the conclusion that the nervous symptoms were dependent upon a specific lesion of the brain,—most probably meningitis,—causing paralysis of the external recti muscles, and that the same diathesis was the cause of the optic neuritis. A closer study of the case has convinced

me that I was wrong. In the first place, the patient does not present a single symptom which lead is not capable of producing, while there are some absent which we should have at least expected in syphilitic disease. Shortly after her admission into our wards her temperature was noted and found to be normal; at least such is the recollection of the nurse, for, unfortunately, the record has been lost. It is most likely that her memory does not mislead her, for had there been any increase we should have continued to use the thermometer. Later in the case the temperature was again observed, and again found normal; and this time, as you have learned from the notes, the observation was recorded. In meningitis, no matter how slight, fever is an almost constant attendant, while on the other hand the gravest cerebral symptoms due to the absorption of lead are not of necessity accompanied by any elevation of the temperature. The delirium, too, which was present on more than one occasion is much more likely to have been caused by the lead than by syphilis; and the same may be said of the muscular tremors. Optic neuritis may, and occasionally does, occur in syphilitic persons, but Mr. Hutchinson and others have shown that it is not infrequently met with in those who work in lead. The only symptom which it was difficult to explain on the supposition that the patient was affected with lead-poisoning was the palsy of the external recti; but the effects of lead manifest themselves in loss of power of other muscles than the extensors of the wrist, and I see no reason why the external recti should not sometimes be the sufferers. In fact, I have recently been told that Mr. Hutchinson has reported cases in which he shows that this has occurred. I need not add that we have other symptoms than those I have been just pointing out which indicate unmistakably the presence of lead-poisoning. The patient denied at first having used lead as a cosmetic, but after the white lead had been found in her pocket she confessed that she had bought it to apply to her face, and had been applying it for at least two years. We have a well-marked blue line on the gums, which still persists, in spite of the treatment by iodide of potassium; and we have a tendency to constipation, which is disappearing under the remedies employed.

The second case is even more interesting than the first. When I saw the patient for the first time she appeared to be suffering from a disease of the stomach, either ulcer or gastralgia; but the discovery of the blue line on the gums the next day satisfied me that I had to do with a case of lead-poisoning. You have heard that she denied having ever knowingly used any preparation containing lead as a cosmetic, but her friends and her sisters were more candid; and there can, therefore, be no doubt that she not only made such a use of white lead, but that she also applied it very freely to the surface of the upper part of her body. For a few days she seemed to do well under the treatment adopted. The paroxysms of pain became rarer and less severe, the vomiting occurred less frequently, generally in the morning, and only occasionally after eating, and she apparently gained

strength. The anæmia, notwithstanding the administration of iron, remained, however, as marked as ever, and the same was true of the muscular soreness.

I was unprepared for the grave change in her condition which I found at my morning visit to the hospital on the 13th. Although fully aware that the symptoms then present might be due to the lead-poisoning, I confess that I had some difficulty in regarding them as anything else than the manifestation of hysteria, to which they unquestionably bore a decided resemblance. It was difficult to look upon them as expressions of serious cerebral trouble, because there was neither heat of surface nor acceleration of the pulse,—which does not of course exclude lead-poisoning,—and because she had given on one or two occasions some evidence that she was of an hysterical temperament. The character of the convulsions appeared, however, to be distinctly epileptiform, with loss of consciousness and foaming at the mouth. In addition to the iodide of potassium, which I directed should be continued, her treatment consisted of a turpentine injection, and cold affusions to the head. Later in the day the resident found it necessary to administer hypodermically a quarter of a grain of morphia and an opium suppository, in order to quiet the excessive restlessness. I saw the patient again the next morning, and learned that she had had another convulsion similar in character to those that preceded it. Her symptoms also indicated that her condition was a more serious one than it had seemed to me the day before. Her pulse was much weaker, and her tongue was heavily furred with a thick whitish coating. She also complained of pain in the nucha, and there was some slight retraction of the head; but I was then, and am still, inclined to believe that she opposed some resistance to my attempt to bend her head forwards. If any doubt had been left as to the serious nature of the case, it would have been dispelled by the results of the ophthalmoscopic examination, which showed the presence of optic neuritis,—a disease which, I repeat, it is now well known occurs as a consequence of lead-poisoning, and the existence of which was fully proven at the post-mortem examination. The results of the autopsy were in other respects confirmatory of the correctness of the view I held. No lesion of the solids of the body was detected which could reasonably be supposed capable of causing death. Congestion of several of the organs, and engorgement of the meningeal vessels both spinal and cerebral, were found, it is true, but these I am disposed to look upon as consequences of the fluid condition to which the blood had been reduced by the prolonged action of lead. In order that the examination of the brain might be made by one who had no preconceived opinion to maintain as to the nature of the disease, I requested my colleague Dr. Hunt to make it. Having done so, he pronounced the brain to be perfectly healthy in all respects, save, of course, that it was anæmic and that there was discoloration of the gray matter,—a condition which is said by Valleix* to be not infre-

quently met with in the brains of those who die of lead-poisoning. With the object of leaving nothing undone that may throw light on this interesting case, I have sent portions of the brain, liver, and kidney to Dr. H. B. Hare, the pathological chemist to the hospital, in order that they may be examined for lead; and I will report to you at some future time the result of his investigation. The effusion which was found beneath the spinal membranes probably took place not long before death, since during the last convulsion the legs were not moved, which was not the case during the previous convulsions; and there was no loss of power observed at the morning visit.

The three cases are further of interest because they illustrate the fact that the same poison may and does frequently produce very different effects in different people. You are aware how various are the forms which constitutional syphilis is capable of assuming; and the same is true to a certain extent of lead-poisoning. The girl with wrist-drop has been under observation for more than three months, and during that time has never suffered from constipation or colic, and has at no time presented evidences of nervous derangement. But the same cause has lighted up in the two other cases a train of cerebral symptoms which has terminated in one case in death, and in the other will certainly leave behind it a decided impairment of vision. The sudden and unexpected supervention of delirium and convulsions upon colic and constipation, which occurred in the former, has, of course, been observed before. It took place in the case which was under my care some years ago, giving rise to the impression that the patient had been drinking, and leading to his arrest.

The cerebral symptoms in lead-poisoning may assume various forms. In some instances the progress of the disease is slow, and the periods of delirium may alternate with intervals of entire consciousness. This was seen in our first patient, who could be said to have been "out of her head" only on two or three occasions. This is not a dangerous form, and generally ends in recovery. In others, as in the case of M. C., convulsions occur with great frequency, and are followed by delirium or coma. In still another form, coma is the only indication of grave trouble. Of all these forms, the convulsive is said to be the most serious.†

The ophthalmoscopic examinations were, I need not say, of great service to us in arriving at a correct conclusion in the first case, and in the second they placed beyond doubt the existence of more than a merely hysterical condition. In making them I have had the advantage of the assistance of Drs. George C. Harlan and W. F. Norris, both of Wills Ophthalmic Hospital. The occurrence of amaurosis in lead-poisoning had not escaped the observation of our predecessors in the healing art, but before the introduction of the ophthalmoscope

† Cerebral symptoms dependent upon lead-poisoning are well described by the following authors: Valleix, *loc. cit.*; Th. and A. Husemann, *Handbuch der Toxicologie*; Jaccoud, *Clinique Médicale*; Stille, *Therapeutics and Materia Medica*; Tanquerel; Brockmann, *Die metallurgischen Krankheiten des Oberharnes*; Wunderlich, *Pathologie*.

* *Guide du Médecin Praticien*, vol. v.

it was impossible to say whether this depended upon simply a loss of the power of accommodation or upon optic neuritis. We are now in a position to make this distinction; and this is a gain of no little importance, inasmuch as the existence of the latter may be assumed to indicate that the system is more fully under the effects of lead than when the former alone is detected. We are, moreover, not to limit our examination to those cases in which complaint is made of a defect of vision, for the inflammation may produce marked changes within the interior of the eye without the patient or her friends being aware of its presence, as in the case of M. C., who always when questioned on the subject answered that she saw perfectly.*

Pathologists have of course explained in different ways the mode in which lead-poisoning gives rise to cerebral symptoms. By some it is thought that they are due to the direct irritation of the lead, but to me it appears much more probable that they are largely owing to the anæmic condition of the nervous centres which is generally present, and which certainly did exist in a marked degree in the fatal case reported by me, in which there was scarcely a symptom present which could not be referred to this cause, and in which there was, judging from the remarkably fluid condition of the blood after death, a deficiency of fibrin as well as of the blood-corpuscles.

It still remains for me to speak of the treatment. In the first case, the use of the iodide of potassium in large doses, combined latterly with iron, has been of decided benefit to the patient. You recollect the condition in which she was first brought before you, carried upon a stretcher; to-day she is able to walk down-stairs unassisted. The internal squint has gone, and she has gained strength and flesh. Unfortunately, I cannot add that the optic neuritis has subsided; it is apparently beyond the influence of remedies. The small quantity of bichloride of mercury which was added to the iodide not long after her admission was prescribed under the idea that there might still be lurking in her system some vestige of the syphilitic poison. The patient has also been taking quinia, and has, I think, been benefited by it.

The same remedies were employed in the second case, and were apparently doing good, when, without warning, a convulsion occurred. Is it possible that any other treatment than that adopted would have saved the patient's life? I think not. Certainly not bleeding or any other depletory measure, for this would have aggravated the anæmia, which was, I believe, the exciting as well as the predisposing cause of the convulsions. These did not seem to be prolonged enough or sufficiently numerous to make it justifiable to have recourse to the inhalation of chloroform; and if a similar case were to present itself to me to-morrow I should treat it in the same way.

I have but a word to add in conclusion, and that is to call your attention to the fact that, in a ward which contains generally about twenty patients, I have had at one time as many as three presenting

symptoms produced by the use of white lead as a cosmetic; and I have good reason to believe that it is sold in large quantities by druggists who know the purpose for which it is bought, although they may be ignorant of the disastrous consequences its use entails. You have had sufficient evidence to-day that its application to the face is far from being harmless; and perhaps some of you may have the power, by making this generally known, to prevent some poor woman from falling a victim to her vanity.

ORIGINAL COMMUNICATIONS.

CURIOSITIES OF COUGH.

Reported to the Medical Library and Journal Association, December 12, 1873.

BY L. ELSBERG, M.D.,

Professor of Laryngoscopy and Diseases of the Throat in the University of New York.

IF, as is often said, the medical specialist be in danger, on account of the limits of his practice, of becoming one-sided and prejudiced, he enjoys as a corrective the advantage of seeing, more frequently than general practitioners, rare and difficult cases, which teach him the relation and inter-connection of diseases of different organs, and of local and general affections. Some years ago, in an essay which I had the honor of reading before this association, I pointed out some curious instances of the connection of throat-diseases with various other derangements of health; this evening I desire to call your attention to some cases of unusual cough which have fallen under my observation during the last twelve months.

I have seen three cases of what I cannot better characterize than as a "dog-cough."

I.—J. S. B., a healthy-looking boy, born and brought up in the country, æt. 15 years, reported to have had some trouble in his throat for several years, came to my office about a year ago, making at irregular intervals a loud barking noise, not distinguishable from the barking of a large ordinary dog. The intervals of quiet lasted from only a few minutes to half an hour. His mother said that this peculiar cough had existed for three or four months, and that previously he had had an ordinary cough for a couple of years, which gradually developed into this bark. He had continually been under medical treatment, with, however, only occasional and temporary benefit; the bark had never been influenced by any medicine, but had become worse—*i.e.*, more frequent—during the last few weeks. The boy's general health seemed unaffected; his respiration, appetite, digestion, evacuations, sleep, etc., were normal; he sometimes, though not frequently, barked during the night, but this did not always awaken him. I found enlarged tonsils, some pharyngitis, and localized inflammation of the upper aperture of the larynx,—*i.e.*, of the free border of the epiglottis, the ary-epiglottic folds, the mucous membrane covering the cartilages of Santorini, and the upper portion of the arytenoid cartilages; just around the upper laryngeal aperture there struck me as being a circumscribed, livid discoloration.

The other two cases resembled this one in the peculiarity of the loud, dog-bark cough; the anatomico-pathological condition, however, was differ-

* Since this lecture was delivered, Dr. Norris has examined sections of the optic nerve, and tells me there is abundant evidence of the existence of inflammation under the microscope.

ent. In neither were the tonsils enlarged or pharyngitis present, but in both the epiglottis and the immediate neighborhood of the entrance into the larynx were more or less affected. In one, a little boy of ten years, there was principally inflammation and swelling of the ary-epiglottic folds; and in the other, a young lady of nineteen, there were, in addition, superficial ulcers like pins' heads on the upper edge of the epiglottis, especially at the angle of junction of the ary-epiglottic folds.

In all three cases the character of the cough was so marked that persons who heard it without knowing its source mistook it again and again for the barking of a dog. I would add that the barking was like the healthy dog-voice; I have known more than once dogs to be suffering from a cough resembling in sound an ordinary human cough, but what these three patients had sounded just like the ordinary dog-bark. All three were cured by local treatment, in conjunction with attention to the general health.

II.—February 14, 1873, Mrs. E. M., of New Haven, æt. 31 years; has generally enjoyed good health until three months ago. Since then, she suffers from frequent paroxysms, consisting of a peculiar hacking cough, combined with retching and straining positively distressing to listen to. The cough itself is indescribable; she does not vomit, but strains so hard as to make one sick to witness it. This continues until she coughs up a little phlegm and matter. She also complains of some pain on the left side, just back of the larynx. On laryngoscopic examination, I found that the left pyriform sinus contained some purulent matter and something dark, and discovered at the bottom two ulcers. When I announced what I saw to the patient, she turned to her husband and said, "There, didn't I always tell you so?" She then told me what she had purposely omitted to relate before,—viz., that her trouble commenced after swallowing some black thread which she had bitten off in sewing, three or four months previously. It remained there ever since, in spite of the terrible attacks of coughing and retching to get it up; but was now easily removed. She had taken all sorts of medicine without benefit; the whole fauces and pharynx were sore and inflamed from the straining and tearing; sometimes she would get up phlegm streaked with blood from the violent efforts. She was exceedingly nervous, and the general health was affected both by her disease and the medicine she had taken.

More than ten years ago I communicated to the Academy of Medicine some observations on diseases of the pyriform sinus, and among them the following case of follicular ulceration:

Louis D., a native of Germany, aged 17 years, working as a tinsmith, after exposure a year and a half before I saw him "caught a severe cold and cough." He had taken all sorts of cough-mixtures, domestic and from doctors, regular and irregular; had been to the German Dispensary, the College of Physicians and Surgeons, etc., etc. Since six weeks the cough had become *truly terrible*,—a ceaseless hacking night and day. When the lad came to me he presented the obvious signs of a rapid consumption; he was extremely weak and emaciated, with a pulse varying from 120 to 130, hectic flush on cheeks, and cold extremities. He could obtain but little sleep, and had also night-sweats; but over-weighing all else was the cough,—constant, irritating, hacking, severe beyond description."*

Since then I have repeatedly found a cough of the utmost severity depend upon disease of the pyriform sinus.

(To be continued.)

MYELOGENIC LEUKÆMIA.

BY H. C. HAND, M.D.

BEING more than ordinarily interested in researches on the development of the blood in the red marrow of bones,—having, indeed, myself published some observations on the subject (*Philadelphia Medical Times*, vol. ii. p. 164),—I was greatly pleased to meet the translation by William Ashbridge, M.D., in the *Times*, vol. iv. p. 102. In the case of Professor F. Mosler, there detailed, we have both the *ante-* and *post-mortem* history of a patient with myelogenic leukæmia.

I desire to call attention to the history of a case which has already been published in the *Northwestern Medical and Surgical Journal* in a series of cases of organic heart-disease, but which possesses far greater interest in this connection.

Bridget McGuire, æt. 70; single; temperate; native of Ireland; in giving her family history states that her mother died of old age, her father, at the age of sixty years, of dropsy with cough, and that one sister died at sixty, after but one week's illness, of hæmoptysis, spitting a great deal of clotted blood every day from her seizure to death. The patient came from Ireland in 1809, since which time she has earned her living by light sewing and lace-weaving, always being careful to preserve good health. She has been delicate from girlhood, and has suffered from palpitation of the heart. When forty-four years old she had some affection of the lungs, which confined her to bed two months. From this she recovered her usual health, and retained it for a number of years.

At the age of fifty-one she was treated by Dr. Mitchell for *heart-disease*, having had quite profuse hæmoptysis, caused by heavy lifting, and suffering from debility, palpitation, and a violent pain in the region of the heart, with tenderness on pressure. Recovery took place from this attack, but she was left subject to occasional exacerbations of a similar character. At the age of fifty-eight her feet swelled; after three weeks the swelling subsided; but from that time onwards she has often had a slight effusion of serum in the feet and legs.

About Christmas, 1869, she commenced to be short of breath, and to suffer greatly from eructations, both day and night, of clear, tasteless water.

October 10, 1870, she was admitted to the Philadelphia Hospital, complaining of dyspnoea, slight, dry cough, a "sore pain at heart," and œdema of the feet.

October 14.—Note made that the expression of the face is intelligent, but anxious. The position assumed is a sitting one in the bed, the recumbent position being impossible. Her complexion is sallow; the lips and extremities bluish; the conjunctivæ dingy. The muscular and adipose tissues are not greatly wasted. The skin is soft and flexible, but cool. The feet and legs are œdematous. She occasionally has slight dizziness; never any headache. The sight and hearing are good. Sleep for the last two months has been impossible in the recumbent posture, and disturbed by smothering sensations even when sitting up. The tongue is of a

Organs under Sight. Transactions of the New York Academy of Medicine, vol. ii. part xii. p. 436.

* See Essay on the Topical Medication of the Larynx and Neighboring

purplish hue. The appetite very poor, and a gripping pain is felt in the course of the œsophagus during deglutition. Abdomen tympanitic. Neither spleen nor liver enlarged. Bowels inclined to constipation.

She has some cough, but no expectoration; says that four years ago she had a severe stitch in the upper side of the chest, the doctor attending calling it pleurisy. The right clavicle is excessively prominent; the percussion-note under it is dull, the respiration harsh. Left side, anteriorly, percussion clear, respiratory murmur feeble, expiration prolonged. Posteriorly, the right side of the chest is much more prominent than the left, while its percussion-note is unduly resonant, and respiration feeble. The left side is dull on percussion; respiration bronchial, with bronchial resonance of voice. Submucous and subcrepitant râles are heard in all parts of the chest.

Heart, no pain at present; impulse normal; movements regular. Its space of dullness extends from the third intercostal space to the base of chest, and from the left edge of the sternum two inches outwards. There is no murmur. Pulse 100, feeble. The veins at the base of the neck are engorged, and pulsate. There is no pain nor tenderness about the kidneys. Urine, specific gravity 1016; no albumen; normal in color and quantity. No pain nor swelling of joints.

October 18.—In the morning she appeared nearly as well as usual, sitting up in bed, but looking somewhat exhausted, and complaining of pain in the legs and a sense of distress about the heart. Very soon after, she died by syncope.

Autopsy twenty-four hours after death.

Sternum.—First and second pieces movable on each other, as are also the third and fourth. Thick, bloody pus exudes when the periosteum is punctured near the movable portions. The cancellated tissue is softened so that the anterior and posterior compact layers can be approximated by pressure.

Lungs.—There are pleuritic adhesions on each side, confining a considerable quantity of straw-colored serum at right apex, at each base, and smaller quantities elsewhere over posterior lobes; the whole amount in each pleural cavity is about one pint.

The pulmonary tissue is emphysematous, except that at the base of the lungs where bathed by the pleuritic effusion, which is dark-colored, it has the appearance of flesh, and sinks readily in water. The whole of both posterior lobes, in fact, floats very low in water, is congested and firm. The bronchial tubes of congested portions contain muco-pus.

Pericardium.—Some old flakes of lymph on cardiac portion.

Heart.—Weight twelve and a half ounces. Cavities enlarged; walls firm, and of nearly normal thickness; valves all water-tight except the tricuspid, which leaks a little. Slight atheroma about the attachments of aortic valves. Right side of heart full of liquid blood, and some soft, dark clots. Left side empty. The blood in the veins is liquid.

Microscopical Characters.—The muscular fibres of the walls of the left ventricle are in an advanced stage of fatty degeneration, being filled with granules soluble in ether, and the striæ of many of the fibres being nearly obliterated. The fibres of the walls of the right ventricle are for the most part free from granules, having only small patches scattered here and there; the striæ are distinctly visible.

The Peritoneal Cavity contains one pint of straw-colored serum.

Liver.—Weight thirty-nine ounces. It is gorged with liquid blood, and is finely mottled with red and yellow. There is a broad (two and a half inches) depression on the upper surface of the right lobe, running from behind forward; the capsule covering this portion is

white, and thickened; a dilated branch of the portal vein (three lines in diameter) runs just beneath. The hepatic tissue contains one or two calcareous nodules the size of a cherry-stone.

Spleen.—Weight twelve ounces; firm; trabeculae prominent on section; capsule thickened, and covered by small flakes of lymph.

Kidneys.—Left, about normal size. Right, weight three and a quarter ounces; its capsule thickened and adherent so as to tear off some renal tissue when removed, leaving the surface rough and granular, and exposing small cysts. Section, dark in color; the cortical portion is scarcely a line deep.

Here, then, was a patient who, as I distinctly recollect her, was suffering with general debility, a feeble circulation, and profound anæmia; and at the post-mortem examination of her body a substance resembling pus oozed out from the cancellated tissue of the sternum. If on one hand it is to be regretted that no examination was made of the marrow of other bones, and no microscopical examination of the blood or of the puruloid liquid from the sternum, on the other hand there is the advantage that the notes were taken (October, 1870) before Neumann's researches had attracted any attention, and consequently at a time when there was no theory to be upheld. The anæmia seen to exist during life and the liquidity of the blood found after death justify the conclusion that the patient was in a leucocythæmic condition. The absence of those lesions of the spleen, liver, and lymphatic glands which usually accompany leucocythæmia, and the unmistakably abnormal character of the marrow of the sternum, together give strong evidence that to a vice of her blood-making marrow she owed the condition of her blood.

Nor is this the only case in which I have seen a like condition exist, although it is the only one of which I have notes. At autopsies of anæmic and emaciated subjects in the dead-room of the Philadelphia Hospital I have not infrequently (I would certainly be within bounds should I say six times) seen the same purulent liquid issue from the broken sternum. More than almost any other condition I have ever seen in the cadaver, it has puzzled me to explain. Not even when studying the changes occurring in the marrow, preparatory to the publication of the article already mentioned, did the condition of the sternum and the general condition of those patients become associated in my mind. Never, in fact, until reading the translation of the report of Professor Mosler's case, did the full solution of the problem fall upon me.

ST. PAUL, MINN., December 6, 1873.

HYPOGASTRIC LITHOTOMY (*The Lancet*, December 6, 1873).—Supra-pubic lithotomy has, in certain cases, a decided advantage over the lateral operation. Mr. Sampson Gamgee reports the case of a little girl, æt. 9, pale, puny, and with a very narrow pelvic outlet, who had long suffered from the presence of a large calculus in her bladder. The size and fixity of the stone, together with the smallness of the outlet, induced him to operate by the hypogastric method. The calculus was extracted, and the wound healed directly. There was no constitutional disturbance, and the patient was discharged, cured, on the fourteenth day.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

SURGICAL CLINIC OF PROF. JAMES R. WOOD.

LIGATION OF THE FEMORAL ARTERY FOR POPLITEAL ANEURISM.

RICHARD C. (colored), æt. 35; male; U. S.; cook; admitted December 15, 1873. The patient gives a good family history; has rarely been ill himself. He has had gonorrhœa several times, however, and has had sores on his penis, but no secondary symptoms. He has been a hard drinker for years. Nine years ago he had an aneurism of the right popliteal artery. Pressure was tried in vain. The femoral artery was then ligated in Scarpa's space, and the patient made a complete recovery, the ligature coming away on the thirteenth day.

Two years ago the patient noticed a pulsation in the left popliteal space. This continued for six months; and then a tumor appeared of the size of a walnut, which gave him neither pain nor inconvenience. He went about his work, paying no attention to the doctors, who told him he had an aneurism. Meantime the tumor increased in size, and about seven months ago it began to give him pain and to swell. The swelling soon extended from the knee to the ankle. The pain and swelling would disappear after the leg had been bathed, rubbed, and bandaged, while the original tumor and pulsation remained undiminished. Still the patient kept at work until two months ago, when the pain and swelling had become so great that he was obliged to go to bed. The swelling increased, and the skin which covered it became so tense that he feared it would burst. At this juncture he was admitted to the hospital. On admission, the patient is a strong, healthy-looking man. He is suffering considerable pain, and can sleep but little in consequence. The left foot, leg, and lower third of the thigh are markedly œdematous, and the integuments are tense and shining. A tumor is found occupying the whole popliteal space and the lower third of the inner side of the thigh. Distinct pulsation can be seen as well as felt in this tumor. The pulsation is expansive, and synchronous with the radial pulse. No thrill can be felt, but a murmur, synchronous with the radial pulse, is heard over the whole surface of the tumor, loudest at the lower portion of the popliteal space. A blowing sound is heard also over the femoral artery above the situation of the tumor. When pressure is made on the artery above the tumor the pulsation and murmur cease, but the size of the tumor remains unaltered. On removing the pressure the pulsation and bruit return.

On making deep pressure over the artery, just above the tumor, the artery may be felt rolling under the finger like a somewhat stiff tube. The following are some of the measurements of the lower extremities:

	Right. Inches.	Left. Inches.
Thigh just above the tumor	14 $\frac{3}{8}$	19
Thigh midway between the knee and the upper limit of the tumor	13 $\frac{1}{2}$	22 $\frac{1}{2}$
Leg over tubercle of the tibia and lower portion of popliteal space	12	20 $\frac{3}{8}$
Knee over middle of patella and middle of popliteal space	14 $\frac{1}{4}$	24 $\frac{1}{2}$
Calf, upper portion	12 $\frac{1}{4}$	18 $\frac{1}{2}$
" middle "	12 $\frac{3}{8}$	17 $\frac{1}{4}$
" lower "	9	15
Ankle	7 $\frac{1}{2}$	11
Around point of heel and across instep	12 $\frac{3}{8}$	15 $\frac{1}{4}$
Around arch of foot and across instep	10	12 $\frac{1}{2}$

On the day of admission the whole limb was wrapped in cotton batting, and eight pounds six and one-half ounces of shot were placed over the femoral artery. A tourniquet was also buckled loosely around the thigh, to provide against accident.

December 16, A.M.—Bowels have moved four times since admission. Patient slept but little during the night.

December 17, A.M.,	pulse 104;	resp. 22;	temp. 99°
P.M.,	" 112	" 22	" 100 $\frac{1}{2}$ °
" 18, A.M.,	" 100	" 20	" 99°
P.M.,	" 108	" 27	" 100°
" 19, A.M.,	" 120	" 28	" 100 $\frac{1}{2}$ °

Patient has quite a brisk diarrhœa. Ordered bismuth. subnit., gr. x, after each passage.

December 19, P.M.,	pulse 116;	resp. 29;	temp. 101 $\frac{1}{2}$ °
" 20, A.M.,	" 112	" 24	" 99 $\frac{1}{2}$ °

Patient slept well last night; has no diarrhœa.

A consultation was held at noon of the above date, and ligation of the femoral artery was decided on. Professor Wood did the operation in the presence of the class. The artery was exposed without difficulty, and ligated four and one-half inches from Poupart's ligament. The edges of the wound were brought together by means of wire sutures, reinforced with adhesive straps. The whole limb was enveloped in cotton batting. Evidences of incipient aneurism of the arch of the aorta, as well as of fatty degeneration of the heart, had been discovered before the operation, and for these reasons the patient took no anæsthetic. He bore the operation, which lasted ten minutes, without flinching.

"At the consultation," said Professor Wood, "the question was of course between ligation of the femoral artery and amputation of the thigh. In the operation we have performed, the dangers to be apprehended are principally three: first, secondary hemorrhage at the time of the separation of the ligature; second, gangrene of the leg from inadequacy of the collateral circulation; third, sloughing of the sac.

"With regard to the first danger, the atheromatous condition of the artery renders it by no means insignificant; but it would have been no less, and not more easily overcome, had we amputated.

"With regard to the danger of gangrene of the leg, I think it is small; for the growth of the aneurism has been sufficiently slow to admit of the establishment of a collateral supply of blood to the parts below it, amply sufficient for their nourishment. Sloughing of the sac I consider to be the chief danger. In that event we should not wish we had amputated, for the patient might yet recover without amputation. More likely, however, we should be obliged to amputate. I have amputated in such a case with success. With such good prospects for success in this case, I consider ligation far less hazardous than amputation. Should the leg die or the sac slough, we still have left two-thirds of the thigh sound, and we may amputate then with almost as good chances of success as now. I believe we have given the man the best chance possible of saving his life as well as his limb."

After-History of the Case.—December 20, 1873, 3 P.M.—Patient has some pain in the tumor, and in the thigh and leg. Ordered McMunn's Elixir, ℥ xl. 4 P.M., pulse 116; respiration 30; temperature 98 $\frac{1}{2}$ °.

December 21, 9 A.M.—Pulse 124; respiration 30; temperature 102 $\frac{1}{2}$ °. Patient feels much more comfortable, but still has some pain in the knee. 8 P.M.—Pulse 120; respiration 24; temperature 101 $\frac{1}{2}$ °. Patient has not slept since the operation. Ordered McMunn, ℥ xxx. Midnight.—Patient still awake. Ordered McMunn, ℥ xx.

December 22, A.M.,	pulse 114;	resp. 24;	temp. 101°
P.M.,	" 124	" 25	" 102°

December 23, A.M., pulse 114; resp. 25; temp. 101°
Slight discharge of pus from the wound.

December 23, P.M., pulse 114; resp. 24; temp. 101°
" 24, A.M., " 108 " 23 " 100°

Patient has no pain; appetite excellent; bowels slightly constipated; some flatus; ordered enema of assafetida. The integuments covering the tumor, leg, and foot are becoming wrinkled.

Measurements.

	Inches.
Thigh just above the tumor	19½
Midway between knee and most superior portion of the tumor	23
Over tubercle of tibia and most inferior portion of popliteal space	17½
Knee over middle of patella and middle of popliteal space	24½
Calf, upper portion	17½
" middle "	17½
" lower "	14½
Ankle	11
Around point of heel and across the instep	14½
Around arch of foot and across the instep	12½

December 24, P.M.—Pulse 112; respiration 32; temperature 100½°.

December 25, A.M.—Pulse 112; respiration 30; temperature 100½°. Small amount of pus is discovered in the wound, and one suture is removed; otherwise patient is doing well.

December 25, P.M., pulse 120; resp. 20; temp. 100½°
" 26, A.M., " 116 " 30 " 100½°
" P.M., " 120 " 26 " 100½°
" 27, A.M., " 124 " 28 " 100°

Patient is comfortable; has no pain, and sleeps better than at any time since the operation. Appetite good.

December 27, P.M., pulse 116; resp. 28; temp. 101½°
" 28, A.M., " 116 " 22 " 98½°

Patient slept well last night. This morning he is very comfortable. The integument over the tumor is wrinkling more and more every day. Tumor gradually decreasing in size. There is still some pulsation in it—not expansile.

1.30 P.M.—Patient while at dinner felt something give way at site of the ligature. On looking down, he saw blood coming from the wound. The house-surgeon was immediately called, but before he arrived patient lost eight ounces of blood. The artery was controlled by digital compression under Poupart's ligament, and by Petit's tourniquet. Patient did not suffer much from shock, but was greatly frightened. Prolabia became pale, and surface cool. Pulse remained quite good. Patient was thirsty; ordered whisky and carbonate of ammonia, also opiates, to keep him quiet. Hot bottles were placed about him.

4 P.M.—Pulse 120; respiration 24; temperature 99½°. Patient is still suffering from fright, but is in good condition.

December 29, 1 A.M.—Involuntary contractions of the quadriceps extensor are noticed. During one of these a hemorrhage happens, patient losing two ounces of blood. Tourniquet is readjusted.

9 A.M.—Pulse 120; respiration 31; temperature 101½°. Patient has been seen every hour during the night, and has not slept at all; still apprehensive of danger. Prolabia pale. Temperature of foot and leg normal.

4 P.M.—Pulse 140; respiration 28; temperature 104°. Patient comfortable.

9.30 P.M.—Surface-temperature high to the touch. Pulse full and rapid. Respiration short and quick. Patient complains of some pain in the epigastrium; is very thirsty. Ordered ice, also tincture of aconite (Fleming's), ℥ i every hour until four doses are taken. The

artery has been controlled by digital compression and tourniquet combined, ever since the first hemorrhage occurred, on the 28th inst.

December 30, 1 A.M.—Patient has not rested well to-night. He feels hungry, and takes ℥ ii of beef-tea. Pulse quite rapid. Surface very warm. Patient suffers no pain.

2 A.M.—Patient has some pain in the leg, and great thirst; otherwise is about the same as at last note. Ordered ice, and McMunn, ℥ xxx. Pulsations in the artery are as strong as ever; they are still controlled by digital compression above the tourniquet.

3.30 A.M.—Patient is sound asleep. Respirations sighing. Pulse still rapid, and skin hot. No change in the character of the pulsations of the artery. Patient awoke once after the last note, but relapsed into a somnolent state.

4 A.M.—Patient more comfortable. Skin not so hot. Pulse less rapid. Temperature of leg good. Patient sleeps most of the time, and has subsultus tendinum.

5 A.M.—Compression still kept up by finger and tourniquet.

9.15 A.M.—Pulse 140; respiration 30; temperature 105°. Patient has slept most of the time since the last note. He feels refreshed; is hungry; takes beef-tea. Temperature of leg still good. Digital and tourniquet pressure still kept up.

12.30 P.M.—Small amount of sero-sanguinolent pus, of fetid odor, noticed in the wound. Dupuytren's tourniquet substituted for Petit's. Artery entirely controlled by it, but digital compression still kept up.

4 P.M.—Pulse 150; respiration 28; temperature 104°.

9.30 P.M.—Pulse rapid and feeble. Ordered tincture of aconite (Fleming's), ℥ ii every hour for three hours.

December 31, 1 A.M.—Pulse 140. Skin cooler. Patient is slightly delirious. Subsultus tendinum. Ordered quin. sulph., gr. v, q. t. h., and ℥ xxx of McMunn's Elixir.

5 A.M.—Patient has grown weaker since last note. Pulse has gradually lost force, and is now very rapid and feeble. Pulsations in external iliac at times cannot be felt. Respirations sighing. Patient is flighty, though easily recalled to himself. Temperature of the leg good. Foot a little cold. Tumor somewhat softer, and skin covering it quite wrinkled.

9 A.M.—Pulse 144; respiration 24; temperature 102°. Patient has slept since last note. He wakes now, and is refreshed; still a little flighty; says he feels well. Pulse fuller, and respirations normal.

1 P.M.—Patient hungry, and eating chicken-soup and oysters. He takes beef-tea and porter through the day.

4 P.M.—Pulse 144; respiration 28; temperature 104°.

9.30 P.M.—Patient has had some nausea, and has vomited. Ordered bismuth. subnit., gr. x; cum cerii oxal., gr. i, to be repeated if nausea should recur. Ordered also milk-punch (milk ℥ ss with whisky ℥ i) every half-hour.

January 1, 12.05 A.M.—Patient awake. Pulse rapid and feeble. Respirations normal. Patient has some abdominal tympanitis. Ordered turpentine stupes. Has not slept for some hours. Ordered McMunn's Elixir, ℥ xxx. Has vomited two or three times since last note. Ordered bismuth and cerium, as above, after each emesis.

2 A.M.—Patient developed tracheal râles rapidly in the last half-hour, and died.

Autopsy.—January 1, 1874, 2 P.M.—All the organs anæmic. Liver and kidneys slightly fatty.

Heart and Arterial System.—At the base of the aortic valves were some atheromatous changes. On the ascending part of the arch of the aorta, just above the aortic valves, was a large patch of atheroma. All the arteries were atheromatous, the left femoral more so than the right.

The recent ligature had ulcerated partly through the artery. Above the ligature a clot of considerable firmness had formed, three-quarters of an inch in length, tapering to a point above, and filling the calibre of the vessel at the seat of ligature. Below the ligature was a clot one inch in length, less firm than the clot above, and not filling the calibre of the vessel perfectly at any point.

The aneurismal sac was firmly adherent to the bone and to the surrounding soft parts; so that, in order to remove it for examination, and to preserve it, the lower half of the femur and the upper half of the tibia were sawn off together.

The sac, as well as the leg and foot, showed no signs of sloughing. The cavity of the sac would admit a man's fist; it was lined with layers of fibrin, and in the centre were clots of blood and fibrin.

The other side of the body presented objects of greater interest. Here the femoral artery had been tied in Scarpa's space, nine years before, by Dr. Gurdon Buck, for popliteal aneurism. The artery was found to be impervious above the seat of ligature, as far as the origin of the profunda femoris, a distance of two and three-quarter inches. Below the seat of ligature the artery was impervious for a distance of two and one-quarter inches. It then became pervious, and remained so for a distance of five and one-half inches. At a point one and one-half inches above the sac it became again impervious. The sac had dwindled to a fibrous cord, two and one-half inches in length, but little larger than the artery itself, and terminating at the bifurcation of the artery. Below the bifurcation the posterior tibial was impervious as far as the peroneal, a distance of one inch; the anterior tibial was impervious as far as the recurrent branch, a distance of three-quarters of an inch.

F. W. CHAPIN, M.D.

TRANSLATIONS.

THE THEORY OF FATTY HEART.

DR. H. CURSCHMANN, of Berlin, makes (*Deutsches Archiv für Klin. Med.*) the following observations regarding a case of fatty heart which was under his care in February, 1870, at which time he was assistant physician in one of the hospitals of Mayence. The patient was a man aged 32 years, by profession a waiter, and, during the course of the affection which terminated in his death, at various times came under treatment, both in the wards of the hospital and also as an out-patient. His first admission into the hospital was in February, 1870. His previous health, up to 1868, had always been good. His parents were both living, and in good health. From his fourteenth year he had been a waiter, and during the last five years he had been in various hotels along the Rhine, and had been compelled to labor very actively. He had not been addicted at any period of his life to the excessive use of spirituous liquors, but, like all his class, had been very irregular in regard to his meals. He had never had syphilis, and had not indulged to excess in sexual intercourse. For two years he had noticed that his strength was failing, that he grew tired upon slight exertion, and suffered from shortness of breath from going up-stairs; but he still continued at his work until compelled by a severe cough, attributed by him to exposure to cold, and an increase of his above-mentioned sufferings, to seek the hospital. At the time of his admission, February 8, 1870, he complained of great weakness, frequent attacks of palpitation of the heart, and a con-

stant shortness of breath, which at times increased in severity to a marked extent. His cough was frequent and troublesome, but accompanied with slight expectoration. He was compelled by his dyspnoea to maintain a half-sitting posture; his cheeks and lips were livid, a moderate amount of anasarca was present over his trunk and arms, while his lower extremities were markedly œdematous.

Auscultation of the lungs revealed a catarrh extending even to the finer bronchial tubes. The impulse of the heart could not be distinctly felt through the thoracic walls, and the area of percussive dullness over that organ was found much increased. The amount of urine secreted was small, and of high specific gravity. Under the use of the infusion of digitalis the symptoms ameliorated, the pulse became fuller, the anasarca diminished, and both the subjective and objective symptoms of the catarrh of the lungs disappeared. The condition of the heart remained about the same: the impulse was weak and indistinct; the sound feeble, but no murmur could at any time be made out. The man was sufficiently well on the 28th of the month to be discharged, at his own earnest desire.

From the 2d to the 17th of May he was in the hospital for treatment for a surgical affection, still suffering from shortness of breath and some palpitation, but had been able to work since his discharge, and did not complain in regard to his general health.

An examination of the heart gave the same result as on previous occasions; the pulse was small and soft, and, in a state of rest, scarcely 60.

On the 2d of June he again presented himself at the hospital, in a much worse condition than at the time of his previous admission. The symptoms were essentially the same as those of the previous attack, but more intense in character. The urine was scanty, and contained albumen; but after the use of digitalis the normal amount was secreted, and the albumen no longer appeared.

On the 4th of July the patient, much improved, was sent to his home in the Thuringian Forest, in the hope that he would there make more rapid progress towards convalescence.

On the 19th of September he came direct from his home to the hospital, and was again admitted, in a much worse condition than at his previous sojourn.

On the 5th of October, in spite of repeated prohibition, he rose from his bed and went to the closet, where he suddenly fell dead.

At the autopsy the body was found œdematous, the skin livid. Upon opening the skull, the meninges were found filled with blood, the brain-substance strikingly light in hue and œdematous, and the ventricles somewhat enlarged and filled with a clear fluid.

The pericardial sac was not changed, and the contained fluid was of normal quantity and character. The circumference of the muscular substance of the heart was quite double its normal size; the increase of the ventricles being proportional. The ventricles, as well as the auricles, were distended with fresh, dark blood. From the right ventricle the clots extended into the pulmonary artery, completely filling it and its larger branches. The walls of the cavities of the heart were thinned: the thickness of the wall of the left ventricle was one centimetre, that of the right half as much, and in some places but one-third of a centimetre. The muscular tissue in almost every portion was of a reddish-yellow color, at some places quite yellow, very relaxed, and quite readily torn. These changes were more advanced in the right than in the left ventricle. The papillary muscles were long and thin, and when cut across showed yellow streaks. The valves of the heart were unchanged, of normal thickness, and capable of perfect closure. A microscopic examination showed that the

muscles had undergone fatty degeneration, and that the striæ of the fibres were indistinct and had in some places vanished. The aorta and its larger branches, so far as examined, were unchanged.

In the kidneys, beginning fatty degeneration was found. The diagnosis of dilated heart with fatty degeneration was made at the time of the patient's first visit to the hospital. The fact of the dilatation was established by physical exploration; and the feeble pulse, and absence of impulse in conjunction with an organ increased in size, manifested a diminution of power. The question whether the diminished frequency of pulse is of pathognomonic value, as asserted by English authorities, is not discussed. No cause sufficient to account for the disease of the heart was discovered at the post-mortem examination. No valvular affection of the heart was present, nor was there anything that could interfere with the course of either the greater or the lesser circulation. The supposition that was made during life, that the changes in the liver and kidneys were secondary in their character, was also supported by the autopsy. The first change that took place in the heart was an excentric hypertrophy, affecting both sides, followed by fatty degeneration and consecutive thinning of the muscular walls of the heart. This conclusion would have been warranted by the anatomical conditions found at the examination, even if accurate and continued observation during life had been wanting, for it would not be possible that so great a dilatation could take place in a heart of normal size. It would be possible only in a heart which was already increased in size and then underwent dilatation. In answering the query as to the cause of original excentric hypertrophy, it must be established, as it was by the autopsy, that there existed no perceptible mechanical cause. But, inasmuch as the microscopic examination revealed only a true muscular hypertrophy, and as this form of hypertrophy is, as yet, attributed only to mechanical causes (true hypertrophy from work, of Rindfleisch), something which is not demonstrable on the cadaver must have acted during life in a similar manner. This being premised, it is easy to bring forward as the origin of the excentric hypertrophy in this case a cause similar to that given in the observations of Traube,—namely, severe and prolonged bodily exercise.

Upon the supposition that this was the cause of the hypertrophy, it is easy to explain the proportional involvement of both sides of the heart. The continued muscular effort of the left side, together with the reaction from the increased pressure of the column of blood in the aorta and its branches, would furnish the cause of the increase of the arterial side of the heart; while upon the other side of the organ a like effect would result from the increased activity of the respiratory function, and consequent disturbance of the lesser circulation. After the hypertrophy had existed for some time, the patient meanwhile continuing to make the exertions to which his diseased state was due, fatty degeneration began. At the time of the first admission of the patient into the hospital, eight months before his death, his heart, although in a state of fatty degeneration, still had power enough to enable him to attend to his work until an intercurrent attack of bronchitis overcame the force of the diseased and weakened organ, and forced him to his bed. At the time of his death, the relaxed heart still had force enough to maintain the circulation while the patient remained quiet in the horizontal position; but when he stood up and attempted to walk, the task was too great for it: a sudden paralysis of its functions took place, and an acute œdema of the brain occurred, resulting in instant death.

WM. ASHBRIDGE, M.D.

ANEURISM OF THE EXTERNAL ILIAC (*The Lancet*, December 20, 1873).—Mr. Wheelhouse reports the following interesting and unusual case: A man, æt. 31, of temperate habits, applied at the infirmary for treatment; and, on examination, there was found a large pulsating and expansile tumor in the right iliac fossa, reaching from Poupart's ligament upwards to within two inches of the umbilicus, and extending in an outward direction almost to the spine of the ilium. It was about the size of a small cocoanut, hard and firm at the lower part, and softer in the upper portion, with pulsations and dilatations synchronous with the pulse in the left femoral artery. The swelling appeared to be connected wholly with the external iliac artery, but to extend above and overlap the common iliac; and, although pressure could not be made on the latter sufficient to stop the beating, it was easily controlled by pressure on the abdominal aorta just above its bifurcation.

Treatment by compression was determined upon; chloroform was administered until the muscles were relaxed, when ether was substituted, and its action kept up continuously for five hours. Lister's large abdominal tourniquet was applied just over the umbilicus, and slowly screwed down until the flow of blood through the aneurism was arrested. In about two hours, the foot becoming cold and blue, the tourniquet was unscrewed slightly; pulsation in the tumor returned, and it was at once reapplied. Two hours later the right limb was blue to the groin, and the left to the knee. Pressure was then slightly relaxed, the tumor being much harder, but still perceptibly pulsating. At the end of another hour both limbs were black, and the body was blue as far as the tourniquet, which was then removed gradually in fifteen minutes, a quarter-turn of the handle being taken every minute. The tumor had ceased to pulsate, and was firm and hard. The limbs were wrapped in wool, and a hypodermic injection of morphia given. On the following day pulsation returned in the tumor with considerable force, but slowly diminished; and by the next evening the tumor was almost fully reconsolidated, and both limbs were normal as to warmth. The cure was complete and permanent.

THE PHYSIOLOGICAL ACTION OF OZONE (*The British Medical Journal*, December 13, 1873).—Dr. McKendrick and Mr. Dewar, in the course of some experimental investigations with animals, found that—

1. The inhalation of an atmosphere highly charged with ozone diminished the number of respirations per minute.
2. The pulsations of the heart were reduced in strength, and this organ was found beating feebly after the death of the animal, which showed that life was not destroyed by direct action on the heart.
3. The blood was always found in a venous condition in all parts of the body, both in cases of death in an atmosphere of ozonized air and of ozonized oxygen.
4. Ozone exercised a destructive action on the living animal tissues if brought into immediate contact with them, but it did not affect them so readily if they were covered by a layer of fluid.
5. Ozone acted as an irritant to the mucous membrane of the nostrils and air-passages, as all observers had previously remarked.

VACCINATION FROM A VARIOLOUS PATIENT WITHOUT COMMUNICATING SMALLPOX (*The British Medical Journal*, December 13, 1873).—During an epidemic of smallpox in a small town, a boy, fourteen years of age, was vaccinated; the arm took well, and about a dozen persons were re-vaccinated from it. On the thirteenth day the boy went to bed with an attack of confluent smallpox; was very ill for a week, and then rapidly recovered. No variola was communicated in any of the cases, and all the arms took well.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 17, 1874.

EDITORIAL.

OUR NEW CHARITY.

AMID the multiplicity of charities which distinguish the progressive civilization of the times, and which in their broad beneficence seek to alleviate human misery, there has been, until recently, in this community, one class for which no organized effort has been made,—a class which on no principle, it would seem, should thus have been left outside the pale of humanitarian and Christian helpfulness.

While the enemies of society, the murderer and the burglar, have been made the objects of philanthropic endeavor, no hand has been outstretched to rescue from utter ruin those who, but for one false step, were worthy members of the community.

Surely, if deliberate, calculating fraud, villany, and outrage do not exclude their perpetrators from helpful pity, one effort at least might well be allowed in behalf of those whose transgression, however great, illustrates human infirmity rather than depravity. Efforts to relieve and reclaim are not arguments in extenuation; but "Go and sin no more" comes to us with a sanction which we dare not despise.

To the shame of our great city, the class of unfortunates alluded to has hitherto had but three alternatives,—murder, suicide, or the Almshouse. Of the inevitable results following exposure to the associations of that institution, it is not necessary to speak. For such as these, over its portals might

well be written, "Abandon hope, all ye who enter here!" Apart, moreover, from any claim to sympathy which may be urged in behalf of the erring ones, there can be no question as to the propriety of securing for their innocent offspring more favorable auspices than a birth in the County Poor-House would afford.

Impressed by considerations like these, a few gentlemen met together about one year since, to devise some plan by which, even if the sorrows of these deluded creatures might not be mitigated, the necessity of a life of open shame should at least be spared them.

As the result of the conference, the STATE HOSPITAL FOR WOMEN AND INFANTS was developed, a Board of Governors and a Medical Staff were organized, a house (No. 1718 Filbert Street) was rented, and, thanks to the energy, enterprise, and unremitting industry of a few ladies, whose co-operation had been solicited, the house was comfortably furnished. An excellent matron has superintended the internal economy of the house; and the periodical visits of the ladies' committee have contributed in no small degree to the success of the undertaking, and to arrangements by which discharged patients could reputably maintain themselves.

During eleven months since the opening of the hospital, forty patients have availed themselves of the asylum thus afforded; and eighteen are now either under its roof or registered for early admission. No loss of life has occurred among the patients; and homes have been provided, by adoption or otherwise, for most of the children born in the institution.

Another object contemplated in the establishment of the hospital was a provision for the treatment of worthy women requiring skilful medical care and nursing, to enable them to maintain their families instead of dragging out a miserable and painful existence, not only helpless, but a burden to others.

Either class of patients is required, when able, to contribute according to their ability to the support of the institution; but very many must be provided for out of the funds of the hospital.

For the objects of this new charity, thus set forth, a most earnest appeal is made by the Board of Governors. The needs of erring and suffering women, the reasonable hope that they may not only be saved from greater error or suffering, but restored to lives of usefulness, are the arguments on which the appeal is based. Whether the enterprise shall succeed, depends upon the benevolence and the Christian convictions of the community. It will

be a sad commentary upon the intelligence of our vaunted philanthropy if frailty must needs degenerate into depravity before succor is tendered,—if the Midnight Mission and the Magdalen Asylum must remain the only or the nearest cities of refuge.

The President of the Board of Governors, Dr. J. W. White, will be happy to receive substantial encouragement for this worthy enterprise.

SELECTIONS.

EUCALYPTUS GLOBULUS: ITS USE IN THERAPEUTICS AND ITS VALUE AS A FEVER-DESTROYER.

THE therapeutic value and uses of the *Eucalyptus globulus* are thus described by Dr. S. Ringer in the *London Medical Record*:

In March, 1870, M. Cloez announced that *Eucalyptus globulus* consists of chlorophyl, cellulose, essential oil (eucalyptol), resin, tannin, lime, and alkaline salts. M. Debray (*De l'Eucalyptus Globulus*, Paris, 1872) and M. Rabuteau (*Communication à l'Académie des Sciences*, November, 1872) confirm these researches. Eucalyptol, a liquid camphor, $C_{10}H_{18}O_2$, possesses almost all the active properties of the plant, which does not contain an alkaloid. When applied to mucous membranes, eucalyptol excites congestion according to the strength of the application. A few drops produce a sensation of coldness in the mouth, whilst one or two grammes (15.5 to 31 grains) excite disagreeable warmth in the mouth, and pain in the stomach and intestines. A small dose promotes appetite, a large one destroys it.

Gimbert employs small quantities of the essential oil, on account of its antiseptic and stimulant properties, in tooth-powders, gargles, eye-washes, and applications to wounds, especially unhealthy wounds. It can be given in capsules; and, by administering it with food, we avoid irritation of the œsophagus or stomach.

A moderate dose of eucalyptol, ten to twenty drops, at first accelerates the pulse, produces pleasant general excitement, shown by irresistible desire for moving about, and a feeling of buoyancy, increased appetite, strength, and sexual appetite. It is an intoxicating medicine, but, unlike opium or a large dose of alcohol, these effects are not followed by brutishness and torpor, but produce a general calmness and soothing sleep. Intoxication is not constant; often it only stimulates. M. Gubler says this excitement may amount to fever; and Gimbert believes that he has produced fever in a dog by subcutaneous injection. M. A. Sicard suffered from a severe attack of migraine after inhaling eucalyptol. In one case it produced cerebral congestion, with much excitement, and in another painful palpitation of the heart. This essential oil, however, rarely provokes these symptoms, and in strong men only after ten or twelve drops, while five to six drops may produce them in nervous persons.

It affects animals as man. They become active, and their senses are made more acute. Excitement is followed by tranquillity and lethargy. Arterial tension is diminished; the temperature falls. Circulation is stimulated by the action of the remedy on the sympathetic. Even moderate doses, if continued for some time, produce an asthenic state. The temperature falls a degree to a degree and a half below natural. The pulse becomes less frequent, and may fall to fifty beats per minute. The senses (and the muscular sense) are

blunted. The functions of the brain are unaffected, there is no stupor, and the size of the pupil is unaltered. The reflex functions of the cord are depressed. These symptoms, rare in young and vigorous people, but more easily produced in old persons, may excite alarm, but are without seriousness, and are removed by a cup of coffee. Eucalyptus, when fatal, kills by destroying the excito-motor functions of the cord; the temperature also falls considerably. An old man with vesical catarrh took, by mistake, eighty drops of eucalyptol, which produced feeling of internal heat and paralysis of the extremities. He had only an objective consciousness of his extremities, and when he shut his eyes he was unaware of their existence. When he wished to move his arms or legs they obeyed him imperfectly, the movements being feeble and disorderly. The sphincters retained their tonicity. A cup of coffee removed these symptoms.

Gimbert says there is a close resemblance between eucalyptol and bromide of potassium. He thinks the decline of the temperature important, and that it will guide us in the employment of this remedy, for in poisoning it falls rapidly; and hence the thermometer must be employed when we administer this medicine to produce its sedative effects, as in scarlet fever, tetanus, or other acute illnesses. Dangerous results may be averted by a few cups of coffee.

As in some doses it stimulates the sympathetic and promotes capillary circulation, he recommends it in congestions and paralysis of the capillaries. It will disperse many cerebral and pulmonary congestions, but whilst serviceable in chronic bronchitis, it overstimulates in acute. Piles sometimes disappear during its administration, perhaps from the local effects, but most likely from its effects on the pelvic sympathetic. In large doses the stimulating effects of this essential oil are slight, and it soon produces asthenia and then paralysis.

Eucalyptol is absorbed by the stomach and lungs. It is eliminated by the lungs (for the breath smells of it even after an anal injection), the kidneys, and skin. In its passage through the lungs it contracts the capillaries, promotes circulation, and hence deepens respiration, and thus in lung-complaints it removes congestion. Elimination may excite irritation of the bronchial tubes (shown by increased cough and hæmoptysis if there be tubercle) if it be administered in too large doses or in unsuitable cases. Gimbert is doubtful concerning its usefulness in checking hæmoptysis; he thinks it may be good where the capillaries only are ruptured, but in hæmoptysis due to softened tubercle he considers it highly dangerous.

It is eliminated by the kidneys in an oxidized form, and makes the urine smell of violets; the powder and tincture, however, produce a herbaceous smell, or leave the smell unaffected. Gubler believes it is chiefly eliminated by the lungs. It greatly increases the elimination of urea: thus, Gimbert usually passes twenty grammes in the twenty-four hours, but under the influence of this medicine he voided forty grammes in the same time. The urine is yellow and clear after eucalyptol, but red after the powder. The essential oil escapes through the skin, rendering the sweat odorous and sometimes producing eruptions. Gimbert gives the following conclusions. It is an antiseptic, by preventing decomposition of organic substances, and particularly of blood. It is a powerful general stimulant, through its primary action on the nervous centres and sympathetic, thereby quickening the capillary circulation. Through its influence on the nervous system, it is antispasmodic. By diminishing the excito-motor activity of the cord, by lessening animal combustion, the frequency of the respiration, and the circulation, it becomes a febrifuge and sedative.

He recommends as applications for neuralgia the essential oil, a few drops sprinkled on flannel, or the following liniment: Eucalyptol, eight grammes; oil of sweet almonds, forty grammes. Internally, he prefers either the essential oil or a liquid extract, preferring it to the powder, which is bulky and difficult to digest. Burning the leaves removes bad smells from sick-rooms, and the fumes inhaled afford relief in chronic bronchitis. As cigarettes, the leaves are useful in humid asthma.

Dr. A. B. Stout merely confirms many of the conclusions of the previous writer. When the empyreumatic oil of the leaves is evaporated, it diffuses an agreeable odor throughout the house. He considers that the oil is allied to creasote and to pyroligneous and carbolic acids; hence its disinfectant and antiseptic qualities. He believes that the powder of the dried leaves scattered in trunks and among clothes will be as useful as camphor or tobacco in driving away or destroying moths and insects, and more agreeable. It is very valuable as a sedative and antiseptic in asthma, throat-diseases, nasal catarrhs, and affections of the mucous membranes.

Like Gimbart, he uses a concentrated tincture (one part of spirit to one of liquid extract), and employs this as an inhalation, which quickly relieves the spasms of asthma. He adds a tablespoonful of the tincture to the boiling water. Cigarettes made with coarsely powdered leaves are anodyne and antispasmodic.

Eucalyptus globulus (blue gum-tree) is a native of Tasmania, but is largely cultivated in the south of France, Spain, Algiers, etc. Dr. Lorinser (*Wiener Med. Wochenschrift*, No. 43, 1869) published some cases of intermittent fever successfully treated by a tincture in two-drachm doses made from the leaves. Dr. Bohn (*British Medical Journal*, March 2, 1872, from *Berliner Klin. Wochenschrift*, February 26, 1872) finds it useful in the fever of hectic as well as ague. Dr. Joseph Keller (*British Medical Journal*, May 11, 1871) treated 432 cases with this remedy; 71.76 per cent. were cured, 28.24 required quinia in addition. Of the 310 patients who were cured, no paroxysm occurred after the first dose in 202. Of 118 cases in which quinia had been given unsuccessfully, 91 recovered under the use of eucalyptus. Dr. Keller believes the plant grown in Austria is less efficacious than that imported from Australia. He considers it of especial use in obstinate ague which has resisted quinia, and that the average duration of treatment by eucalyptus is shorter than that by quinia. He uses a tincture made from the leaves (ten pounds of the leaves yielded twenty-five quarts of tincture). The average dose was two drachms, and the average quantity used for each patient was seven drachms.

Dr. Maclean (*The Practitioner*, November, 1871) recommends this medicine for the dyspnoea occurring in thoracic aneurisms and heart-disease. It should be smoked in a pipe, with or without tobacco, or the leaves may be made into a cigarette. If the dyspnoea be too severe to permit smoking, the patient should inhale the fumes from the burnt leaves.

He found that such discharges are capable of exerting a deleterious influence on the organism, and that gastric and intestinal catarrh, artificially produced, increases the liability to be affected by them. Air is capable of carrying with it particles of choleraic evacuations, and of producing very injurious effects; when the cholera-evacuations were disinfected with carbolic acid, or when those of ordinary diarrhoea were used, the inhalation of air which had been passed through them was followed by no evil results. In a like manner air saturated with the fluid from decomposing meat was comparatively harmless. He also found that a current of air passing through non-disinfected choleraic excretions carries with it cryptogamic elements, which vegetate abundantly in a favorable soil; while the same growths from discharges that have been disinfected by carbolic acid are incapable of multiplication; and he believes that choleraic discharges freed from organized elements are capable, by reason of their chemical composition, of producing the same pathological changes as they do when they contain the organized forms.

While the experiments were being carried on, the attendant, who had been exposed for some time to the emanations from the vessels containing the choleraic excreta, had a severe attack of gastro-intestinal catarrh, which recurred twice within a short period. His little daughter, who slept with him, had vomiting and diarrhoea the day after he became ill. Five days after his illness, two cases of cholera (one of which ended in death) occurred in the house in which he resided, which had hitherto been free from the disease. During the microscopic examination of the choleraic discharges, Dr. Högyes had loss of appetite, a coated tongue, and a constant sensation of oppression in the epigastrium; after the researches were complete, these uncomfortable feelings disappeared.

CASES ILLUSTRATING THE USE OF THE PNEUMATIC ASPIRATOR IN SURGERY (*The Boston Medical and Surgical Journal*, December 25, 1873).—Dr. Charles D. Homans reports the following cases in which the pneumatic aspirator was employed beneficially. A laborer, æt. 54, had an oblique inguinal hernia which became strangulated and remained so for three days. The hernial mass was about the size of a hen's egg, and very tender; taxis was tried unsuccessfully for half an hour, and then a fine aspirator-needle was thrust into the tumor, and from three to four drachms of fluid containing bubbles of air were withdrawn. Taxis was then again resorted to, and the hernia immediately returned. No unfavorable symptoms supervened. In a second case of strangulated hernia the tumor was punctured three successive times, but no fluid or gas passed out. The ordinary operation was then resorted to, and the tumor found to consist wholly of intestine tightly compressed, which explains why no fluid or air came from the puncture.

In a case of retention of urine, the bladder not having been emptied for thirty hours, and all attempts to introduce a catheter having failed, the needle was passed into the bladder behind the pubis and three pints of urine were drawn off. The bladder was again punctured on the following day, after which the urine came naturally, no bad effects resulting from the operation.

PERFORATION OF THE DUODENUM (*Vermont Medical Journal*, January, 1874).—Dr. A. P. Grinnell reports the case of a man æt. 55, who was suddenly attacked with severe epigastric pain while walking. The case was deemed one of colic, and was treated accordingly. In six hours the pain was less intense, pulse 80, and general condition apparently excellent; the following morning he rode seven miles to his home, and four hours later his pulse rose to 110, his extremities were cold,

GLEANINGS FROM OUR EXCHANGES.

THE EFFECT OF FRESH CHOLERAIC EXCRETIONS ON ANIMALS (*The British Medical Journal*, December 13, 1873).—Dr. Andreas Högyes, of the University of Pesth, availed himself of the opportunity afforded by the recent epidemic of cholera in that city, to make a series of investigations on the effects produced on animals by the discharges from persons suffering from the disease.

respiration was difficult, and he complained of excessive thirst. These symptoms all increased in severity, and he died thirty-three hours after he was first attacked. The post-mortem revealed a perforation of the duodenum one-half inch from the pylorus, through which had passed into the cavity of the peritoneum all substances taken as food or drink during his illness. An ulcer was discovered near the point of perforation, but no deviation from health was observable in other portions of the intestines or in the stomach. The peritoneum was inflamed over the greater portion of its surface, and large quantities of pus had accumulated in the pelvic regions. The case is peculiar from the absence of prominent symptoms. The pulse was unaffected until a few hours before death. There was no chill to usher in the peritonitis; there was no nausea, vomiting, or tympany, and he had never had any gastric or abdominal pain before the perforation occurred.

RETENTION OF URINE (*The Lancet*, September 27, 1873).—A sailor, æt. 26, after a protracted gleet, became affected with a severe urethral stricture, which finally produced almost complete retention of urine, only a few drops escaping involuntarily. No instrument could be introduced into his bladder. Four leeches were applied to his perineum, and he was ordered to remain in bed. In a short time a fine filiform bougie was passed into his bladder, and was left there for thirty-six hours, when it was followed by a No. 5 French whalebone bougie; larger sizes were then successfully passed until a complete cure was effected. In remarking on the case, Mr. Teeran said that there were few strictures, however severe, which would not yield to a combined assault with leeches and filiform bougies, and they could be employed on the most diseased subjects without the slightest fear. They would also, as a rule, obviate any recourse to operative procedures.

MISCELLANY.

UNIVERSITY HOSPITAL.—At the meeting of the Board of Trustees of the University of Pennsylvania, on Tuesday, January 6, an organization of the new hospital to be connected with the medical department of the institution was decided upon. The Board of Managers is to be composed of eighteen members: five trustees, elected yearly by the trustees; the seven Professors of the regular faculty; three alumni, chosen by the executive committee of the Society of the Alumni; and three contributors, elected by the contributors. The elections of the last six have to be confirmed by the general board of trustees before they are valid. Every person who has given twenty-five dollars is declared a contributor. Four new professorships were created,—the incumbents to serve without salary, and to be entitled Professors in the Hospital of the University: one of clinical medicine, one of clinical surgery, one of clinical obstetrics and diseases of children, and one of ophthalmology. These professors are, with certain lecturers, to constitute the medical staff of the hospital. The decision as to what lectureships shall be created, and the appointment of lecturers, are left to the medical faculty.

The general management of the hospital is to be entrusted to the Board of Managers, but the medical staff is to have the decision of such questions as the division

of beds. The Trustees of the University retain the right to modify the above plan if at any time it should seem best.

We congratulate the Collecting Committee on the great success which their energy and skill have secured for the movement. Including the value of the land, the whole sum secured approximates \$800,000.

THEN AND NOW.—"Formerly, the great aim of the surgeon was to accomplish his awful but necessary duty to his agonized patient as rapidly as possible, and a clinical clerk, with a watch, always stood by to note the time so occupied. Mr. Herbert Mayo performed amputation at the hip-joint in ninety seconds. Mr. Edward Hutton amputated the middle of the thigh in seventy-eight seconds; and I have heard Jobert de Lamballe pronounce, not very slowly, the words, *un, deux, trois*, while he, with lightning speed, removed an arm at the shoulder. We have changed all this. We operate, like the sculptor, upon an insensible mass; we go carefully through our work, and, although accomplishing it as quickly as we can, we do not count the seconds."—*Prof. Quinlan*, in *Medical Times and Gazette*, November 8, 1873.

ARTIFICIAL BUTTER.—This new commodity, manufactured from beef-suet, having met with an extensive sale in London and Paris, is now being introduced by M. Paraf into the markets of New York and Boston. We must admit that the single specimen seen by us had both the appearance and taste of ordinary firkin butter. The butter is made from the yellow, tasteless, and odorless oil that is obtained from beef-suet. This oil is placed in churns, with one-fifth its weight of sour milk, and churned until an emulsion is formed, annatto being added to give it the required color. It is then cooled, and worked, and salted like common butter.—*Boston Medical and Surgical Journal*.

NOTES AND QUERIES.

BLUE PUS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

In the last number of the *Times*, December 27, under the head of "Notes and Queries," Dr. Cohen reports a very interesting case of the discharge of *blue pus* from an abscess due to laryngeal chondritis, and asks for "any information on this subject, communicated personally, or through the medium of the *Times*."

In the *British Medical Journal* for December 13, 1873, under the heading "Cyanopuon Laryngis: Thyroiditis with Blue Suppuration," is the record of a case by Sir G. Duncan Gibb, M.D., which is almost a duplicate of Dr. Cohen's.

Dr. Cohen says he was unable to determine the location of the abscess, but was inclined to believe it "connected with the cricoid cartilage." Dr. Gibb says the abscess in his case was "consequent upon inflammation of the ring of the thyroid cartilage," and upon puncturing it "a drachm and a half of pus was evacuated, of a dark blue color, not quite so dark as Prussian blue, but more of an azure tint." For a week some discharge of the blue pus continued; after this, though pus was discharged, it was not discolored; and by the twenty-fifth day the opening had closed, and the patient was considered cured.

The original seat of the trouble, according to Dr. Gibb, "seemed to have been beneath the perichondrium of the thyroid cartilage," and although "in the laryngeal mirror the integrity of the larynx was seen to be perfect, and the voice was good, whether in speaking or in attempts to utter

contralto notes," yet necrosis or other trouble of the thyroid cartilage was feared. However, the case occurred in October, 1870, and he says two years have now elapsed without any subsequent trouble.

Dr. Gibb refers to a case of his, published in the *British-American Medical and Physical Journal* for September, 1850, which has been quoted by Mr. Holmes Coats in the article "Abscess" in Holmes's Surgery, and to another brought before the British Association for the Advancement of Science, in 1864, by Dr. Herapath. Dr. Gibb, in experimenting to determine the nature of the discharged fluid, says,—

"1. Liquor potassæ added to the blue pus discharged the blue color, which it does with Prussian blue.

"2. The addition of dilute nitric acid for the most part restores the blue color, which it also does with Prussian blue.

"3. Some of the pus was evaporated to dryness, and ignited; the calx, acted upon by a solution of the ferrocyanide of potassium, gave a distinct alteration of Prussian blue."

The patient had not been taking any preparation of iron recently. Dr. Gibb looked upon it as "due to some physiological change analogous to that which gives rise sometimes to indigo in the urine," and places the case on record as "unique in its combination of thyroditis running into suppuration, the pus being charged with a salt of iron, giving to it a decided dark blue color."

In the *Archives Générales de Médecine* for December, 1873, there may be found a very interesting paper by M. Maurice Longuet, entitled "Mémoire pour servir à l'Histoire de la Coloration bleue des Linges à Pansement," in which he records what may be entitled an "epidemic of blue suppuration," for in his ward in La Charité he had twenty-two cases. M. Longuet objects to the term *blue suppuration* which has hitherto been used to designate such cases, for he was able to produce the blue coloration on the sound portions of the bodies of some of his patients who were yielding the *blue pus* simply by dressing the parts in the same manner as the wounds. Unlike the reaction in Dr. Gibb's case, Dr. Longuet, on repeating the experiments made by Dr. Rouher, of Strasburg, in 1860, found, as he says, that "ils rejettent bien loin cette idée qui attribuait l'apparition de cette teinte à la production du bleu de Prusse ou de phosphate de fer aux dépens du fer contenu dans le sang et des phosphates alcalins ou des combinaisons cyanurées séparées des liquides animaux par suite d'une altération quelconque."

He, however, closes the first part of his article by acknowledging a difference between the *blue pus* of open wounds and that which is "*primi-tivement bleu*," as flowing from a freshly-opened abscess.

The coincidence between Dr. Gibb's and Dr. Cohen's cases—both coming from the cartilages of the throat—would predispose one to think that the laryngeal cartilages, or perhaps cartilage *per se*, were essential to its production; but M. Longuet says that in the practice of M. Richet at the Hôtel-Dieu, early in last year, he saw *blue pus* flow out of an abscess of the breast at the moment of lancing it.

JOHN D. JACKSON.

DANVILLE, KY., January 2, 1873.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

In looking over the number of your journal for November 8 I came across an article entitled "Is the Presence of the Hymen a Proof of Virginity?" by Charles W. Brown, M.D. As I have just had a case in which labor was complicated with the presence of the hymen, the article attracted my attention, but on close inspection I found it rather indefinite.

We find that Dr. Brown makes the following statements: "Upon examination I found the hymen *intact*, and *quite firm and rigid*;" continuing, he tells us that at the lower part of the membrane was a small aperture through which he was unable to introduce the tip of his little finger without some difficulty. The parts were *excessively tender*; this small aperture was gradually dilated by constant pressure of *two hours*; at the end, he was able to introduce his first and second fingers, and find out the condition of the uterus; this being done, an opiate was given, and exit doctor for three hours, *while the hymen makes its exit not to return*; for it is not mentioned *after* this. Now the question arises, What became of the hymen? Did it *dilate* with the uterus? Did it rupture, or did the doctor operate?

The first is not likely to have occurred; and his description would lead us to infer that it was too rigid to rupture, for, according to his statement, after a constant pressure of *two hours* the orifice was only large enough to admit of the introduction of the first and second fingers, and that with difficulty.

The third can be answered by a negative; for, had the doctor operated, he would not have omitted reporting it. Now, again we repeat, What became of the hymen? for we see that labor has been completed by forceps. Now, if the hymen has remained intact,—for as such the doctor

leaves it at his first visit,—he must have applied the forceps and delivered the child through an opening of an inch and a quarter in circumference,—a thing highly improbable.

I remain yours, respectfully,

EUGENE P. BERNARDY, M.D.,
1011 Walnut Street, Philada.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I have noticed the article which appeared in the last issue of the *Medical Times* under the heading of "Notes and Queries," selecting me as a subject through whom a thrust at the dignity of the dental profession might be made, and implying my professional status as being questionable. I trust you will do me the simple justice to publish a brief reply. First, I am a regular graduate of dentistry. Second, I have adopted the administration of nitrous oxide for the painless extraction of teeth as a *special business or practice*. I do not practise dentistry, therefore the dental profession is not in any manner responsible for my business. My position in relation to the dental profession may be likened to that of the apothecary in his relations to the medical profession. The medical practitioner would not enjoy being obliged to compound his prescriptions; and the manufacture and administration of nitrous oxide involve so many troublesome details that it is a like convenience to the dentist to be able to send his patient to some one who makes a special business of that branch. The fact that I advertise renders me ineligible to become a member of the dental societies; and, being fully aware of this, I have never sought to become one. Therefore I am not a suitable subject through whom to make a thrust at the status of the profession. Neither am I a proper subject for unkind or personal criticism. I am conscientiously following a humane calling, and know that I am doing a vast amount of good in relieving the sufferings of my fellow-beings, and have every reason to believe that I enjoy the confidence and respect of the majority of our most eminent men in the medical and dental professions, and of the people of Philadelphia. Dentists in regular practice who have attempted to use nitrous oxide have generally been discouraged in using it, and many have abandoned it as an anæsthetic; why? It is because it is a very peculiar business, requiring great experience to enable one to make it successful. I am charged, because I have made use of the public press to place my name and business before the public, with violating my professional trust, and ignoring the "code of ethics" of the profession. To say the least, this is a discourteous fling, when it is considered that had it not been for the public press the community would not be reaping the benefits of this great boon, as the professions did not, and would not, accept it in the character of an anæsthetic until it became so popular through this medium that they were obliged to award it position as such.

Trusting the next effort made to impugn the status of dentistry as a profession may find a more suitable scapegoat than your humble servant,

I am, very respectfully, yours,

F. R. THOMAS, D.D.S.

Philadelphia, January 8, 1874.

[We insert the letter of Dr. Thomas with pleasure, and take the opportunity of stating that the gentleman who wrote the answer to "Dens" was mistaken in his qualified assertion that the dentists have no code of ethics. Leading dentists inform us that Dr. Thomas—as he himself states—is not recognized by the dental profession as belonging in its ranks, and one sitting in authority tells us that he holds the same relation to the dental profession that Kolbe the splint-maker, or Smith the leecher, does to the medical profession. Like ordinary folk, we thought it was the function of dentists to extract teeth, and, when we saw dentists of standing recommending patients to Dr. Thomas for the removal of sinning bicuspid and molars, concluded he was a dentist—beg pardon, an oral surgeon. It seems he is not. What with seeing oral surgeons amputate limbs, remove arachnoid tumors, cut, slash, divide everywhere, and with hearing that men who extract teeth are not oral surgeons, our finite mind is very much befogged. It's here you see it and there you don't, until under what thimble the ball is we can't tell.—ED. P. M. T.]

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 6, 1874, TO JANUARY 12, 1874, INCLUSIVE.

CAMPBELL, A. B., ASSISTANT-SURGEON.—Assigned to duty at Fort McIntosh, Texas. S. O. 1, Department of Texas, January 3, 1874.

SATURDAY, JANUARY 24, 1874.

ORIGINAL COMMUNICATIONS.

SPINAL CONGESTION AND LOCOMOTOR ATAXIA.

BY GEORGE M. BEARD, M.D.

SPINAL congestion is a condition which, though long recognized by neurologists, is yet by the mass of the profession usually ignored, or confounded with various other diseases. It is unfortunate that this disease is not more correctly and thoroughly described in lecture-rooms and in our text-books of general medicine, for these reasons: 1. It is an affection not infrequent, and, as it sometimes comes on suddenly, it is likely to fall under the observation of the general practitioner. 2. It is very susceptible of treatment, provided that treatment be judicious. 3. When neglected, or improperly treated, it sometimes goes on to serious and incurable structural lesions of the cord, with the symptoms of permanent paralysis of motion, or of sensation, or of both.

There is no one symptom that certainly indicates spinal congestion; but there are a large number of symptoms which, when taken together, and studied with the history of the case, will enable us to make out the diagnosis with perhaps as much accuracy as we are wont to make out the diagnosis of congestion of the lungs or the first stages of pneumonia. The group of sensory and motor symptoms that are caused by spinal congestion is as follows. I give them in their anatomical order, rather than according to the degree of their relative importance:

1. *Headache.*—The pain may be on the back, or top, or on the front part of the head. The nerves that ache are those which take their origin in the cervical region of the cord or in the lower part of the brain. There may be tender points in the crown, or on the forehead, or on different parts of the back or sides of the head.

2. *Stiffness of the neck, with tenderness and pain in the cervical vertebræ.*—This stiffness may be so great as to suggest the idea of rheumatism, or a common cold; and patients thus affected frequently say that they have taken cold, or that they have the rheumatism in the neck. On attempting to turn the head, pain arises, and sometimes the patient acts as though he had torticollis, or wry neck, which is an entirely different affection. To superficial observation the patient gives every appearance of being a sufferer from muscular trouble, and it is no strange thing that this affection so often passes for rheumatism. The muscles, however, have nothing to do with the matter, nor have the nerve-branches. The disease is in and around the cord, and it is in and around the vertebræ that pain and tenderness appear.

3. *Heat and pain down the spine, with or without tenderness.*—In certain stages, when the congestion is of a subacute character, the pain and heat do not

appear, or, at least, are not constant. The heat and burning are not confined to the narrow region of the vertebræ, but radiate all over the back. Over-exertion, as long standing or walking, or a sudden shock or blow, or the strain of lifting, or the recumbent position, usually aggravates the pain and heat in the back.

4. *Feeling of pressure on the chest.*—This symptom, which to my mind is quite an important one, seems to have been overlooked by writers on the subject. The "feeling of pressure" is one that patients, even when not questioned, frequently speak of, and it suggests, almost always, spinal-cord trouble, though not necessarily of a grave character. Patients in localizing this symptom usually place the hand on the lower part of the breast-bone.

5. *Dyspnoea and palpitation.*—These symptoms would very naturally arise from severe congestion of the dorsal region of the cord, and in a mild form are not uncommon.

6. *Feeling of constriction around the abdomen.*—This symptom has long been recognized. It is, however, not peculiar to spinal congestion, as such. In actual sclerosis of various kinds it also appears, and it is by no means constant.

7. *Bladder and rectal disorders.*—Incontinence with dribbling of the urine, constipation, or diarrhoea, may occur. Constipation is more frequent than diarrhoea. Amazing and persistent flatulence, with rumbling in the bowels, is a symptom that I have often observed.

8. *Excessive sexual excitement, with erections and emissions.*—Sometimes the sexual desire is very annoying, and the capacity for sexual intercourse is increased to an extent at once astonishing and alarming. Patients deceive themselves quite often with the belief that this sudden torrent of sexual desire is a sign of health; but, when read rightly, it is a sign of weakness rather than of strength: it is pathological, not physiological. It is analogous to the startling activity and brilliancy of the brain that sometimes precede insanity, or to the ferocious and gnawing appetite that attends the early stages of dyspepsia. Excessive functional activity is a characteristic, not of health, but of disease.

9. *Sensory and motor disturbances, of a mild character, in the upper and lower limbs.*—There may be mild hyperæsthesia or anæsthesia,—that is, excessive tenderness in the soles of the feet, or in the fingers, or over the whole surface of the limbs,—or the reverse condition, slight and varying numbness, a feeling as though the limbs were asleep, or just being roused from sleep, as when we first rise after long sitting in a hard chair. A frequent symptom is a *feeling of heat and burning* in the bottoms of the feet,—a sensation as though the patient were stepping on straw, or rubber, or velvet. Then there may be sudden constrictions of the ankle or thigh, as though a cord were tightly drawn about them.

Neuralgic pains of a sharp, shooting, boring, stabbing character run up and down the limbs, and are felt especially in the borders of the feet, sometimes in the arms and thighs.

Among the mild motor symptoms are twitchings of the muscles or of parts of the muscles, the so-called fibrillary contractions. These involuntary contractions of the muscles have been supposed to be diagnostic of progressive muscular atrophy; but this is a serious error, and one that should be corrected as rapidly as possible, for progressive muscular atrophy is a very solemn disease, that generally, though not always, means death. But these fibrillary contractions occur in thousands of cases that never have another symptom of progressive muscular atrophy.

Jerking of the body or of the limbs on going to sleep is a symptom that sometimes alarms the patient more than it ought to, but is really quite inconvenient, and sometimes makes it very hard to get to sleep. Sometimes the body is apparently thrown up from the bed and comes down with a jar and a bounce. When these jerkings are very mild they do not always wake up the patient, provided he is sound asleep.

To all this indictment may be added a weakness in walking, especially in going up-hill or in ascending stairs. Sometimes it is more wearying to stand than to walk. The concussion of riding in springless wagons usually increases all these symptoms. In walking, the patient sometimes feels as though he were wading knee-deep in water.

10. *Fixed paralysis of motion or sensation, or of both, in the limbs, with or without muscular contractions.*—This condition occurs only in very bad or much-neglected cases. When it does occur, it may be accompanied by bed-sores that are hard to heal. The electro-muscular contractility will be diminished, and the æsthesiometer may indicate great anæsthesia.

In looking over this list of symptoms, it is clear that they may, nearly all of them, be referred to disturbance of the nerves of motion or of sensation; which disturbance is due to the compression of the roots of the nerves in the cord, and to the changes in innervation that result from the presence of too much blood in the nerve-centres. A radical and ever-recurring difficulty in making the diagnosis is found in the fact that nearly all of these symptoms, or at least very many of them, may come from precisely the opposite condition, *anæmia*, with exhaustion of the cord. Excess of blood and deficiency of blood in the brain or in the spinal cord express themselves by the same manifestations. How shall we distinguish? He who says that it is never a difficult matter to make the distinction, is either a very great genius or a very great fool. I know of no single disease in the department of neurology that offers so good a test of diagnostic skill as this: he who has mastered this will find the other and graver lesions, so far as they are known, comparatively simple. There are several general facts which, if they are kept in mind and well considered, will help us to obtain a reasonable certainty.

1. *The history of the case.*—Active and fixed spinal congestion usually gives a history of exposure to cold or injury of some sort, that would explain the symptoms. To get this history, we must frequently inquire

into the life and habits of the patient months, if not years, previous. Symptoms that come from exhausted and anæmic cords cannot be referred usually to any exposure, although they may be aggravated by falls or blows or over-exertion.

2. *The symptoms coming from spinal congestion are more or less fixed and permanent, and are usually worse when the patient is in a recumbent position.*

—The patient with spinal congestion is apt not only to be worse at night, but in the morning, or sometimes, I have observed, for several hours after rising. Cords that are simply exhausted are oftentimes relieved by recumbency; though this rule is not so invariable as has been claimed. The symptoms of exhaustion are fleeting, changing and uncertain—to-day they are here, to-morrow there; and to a degree the same is true of the *early* stages of spinal congestion, but not of the later stages.

3. *Spinal congestion is more likely to occur in the sanguine, bilious, and lymphatic temperaments; exhaustion, in the nervous temperament.*—Patients who are generally anæmic and nervously exhausted, and in whom anæmic murmurs can be detected, would be more likely to suffer from exhausted cords than those who are plethoric and hardy. I have long observed that the *majority* of my cases of spinal congestion and the degeneration to which congestion leads are more frequent *by far* among the sturdy and muscular than among the delicate and nervous.

4. *The female sex is less disposed to congestion of the spine than the male sex.*—When a woman presents the symptoms above described, there is a presumption that exhaustion, and not congestion, is indicated. Then the graver forms of spinal-cord disease are less frequent among women than among men. Of ataxic patients, take them as they come in all ranks of society, there are ten men to one woman. I would account for this comparative exemption of women, *first*, by the fact that the nervous temperament prevails in them far more than in men; and *second*, by the fact that they are much less exposed to wet and cold and to those violent mechanical injuries that excite congestion.

5. *The tenderness over the vertebræ is usually much greater when the cord is exhausted than when it is congested.*—In the so-styled spinal irritation, when exhaustion, with anæmia or alternations of anæmia and hyperæmia, constitutes the probable pathology, the vertebral tenderness is frequently very pronounced, as every physician knows. The hyper-æsthesia is so great that the touch of the hand can scarcely be borne. In spinal congestion, this *extreme* tenderness is rarely if ever seen. Tender points can very often, if not usually, be detected in the middle dorsal and middle lumbar vertebræ when sufficient pressure is used, in the various stages not only of congestion, but of sclerosis of the cord. The fancy which some have advocated, that in serious and organic lesions of the cord tenderness of the vertebræ does not exist, has only this basis of fact, that tenderness tends to diminish as the disease of the cord passes from the irritative and functional to the structural and incurable stages; and yet I have seen

not a few hopeless cases of ataxy and of progressive muscular atrophy, where the tenderness of the middle dorsal and lumbar *vertebræ* was not at all difficult to find.

6. *The results of treatment.*—In some cases it is impossible to decide beyond misgiving whether fixed congestion or simple exhaustion is the pathological condition. All the tests above presented fail us, and we are left in doubt, or if not in doubt we may be mistaken. Here comes in the final test,—the result of treatment. The treatment of spinal congestion in an active state is essentially different from the treatment of exhaustion purely; and according as the patient improves or grows worse may we judge whether we are right in our diagnosis. Dr. Sterling tells me that in a case where all the symptoms and history pointed to anæmia of the cord, treatment by phosphorus and strychnine did no good, and some harm; on turning right-about-face and using ergot in large doses, improvement began at once. Strychnine is a remedy of such peculiar power, and has so marked an action on the spinal cord, that it becomes a most excellent means for revising our diagnosis; a few doses may bring forth evil fruit and force us to look elsewhere for relief. Similarly, ergot, when given in large doses, will sometimes tell us in a few hours whether it is or is not the remedy that is wanted. I have seen cases where ergot in the course of two days aggravated all the symptoms, and I have seen cases where it relieved pains connected with spinal congestion in less than two hours.

You will observe that throughout this résumé of the symptoms and signs of spinal congestion I have kept in prominence constantly, at every step, the *radical distinction between a congestion of the cord of an active and fixed character, and a simple hyperæmia of a passive transient character, resulting from exhaustion, and alternating, it may be, with anæmia.*

In spinal exhaustion, there may be very likely a disproportionate quantity of blood in the cord or in some portion of it, especially after over-exertion; but this is a very different state from a permanent and active congestion. It occurs, as I have stated, in very different kinds of temperament, and requires different treatment. In any anæmic, neurasthenic patient, local and temporary congestions may occur in any part of the exhausted nerves: waves of hyperæmia may settle in the lower part of the cord, in obedience to the law of gravity, which the enfeebled vessels cannot resist. Those who have examined the retinas of nervous patients with the ophthalmoscope know how slight an influence is necessary to change the vascular condition of the fundus, how readily the veins and the arteries enlarge and contract under irritation.

Travellers by the region of Lake George are pointed out by the highway near Ticonderoga a natural curiosity in the shape of a double tree: there are two trunks, growing so closely together that they appear to be simply large branches of one tree; but at a distance from the ground they separate, and the one rises into an oak, and the other, I believe, into an elm. Thus it is with functional and organic diseases of the nervous system. They

begin with symptoms so similar that they appear as one, and for some distance in their course they can scarcely be distinguished; but careful study will show that they soon begin to diverge, and in time they diverge so widely that they have little or nothing in common. One goes on to severe disease, perhaps to death; he who is affected with the other may die at any time, but he never dies of that disease. A man may die with a functional disease, but he will not die of it; the disease may be upon him, and he die, but it is not that which kills him.

Treatment.—The treatment of fixed and active spinal congestion consists in the proper use of electricity, especially of the galvanic current,—in the form of central galvanization, if one chooses; and, if other associated symptoms require it, in the form of galvanization of the spine,—and the free use of ergot or iodide of potassium. Faradization with a pleasant and gentle current is also of value in spinal congestion, though usually it is inferior to galvanization. Both currents—faradaic and galvanic—have a most powerful *contracting* influence on involuntary muscles, as I have shown by a large number of experiments on dogs, rabbits, and on the dead subject. I have experimented with both currents on the involuntary muscular fibre of the intestines, the stomach, bladder, and spleen, and have confirmed repeatedly the statements which have been made in regard to the contracting power of electricity on these organs. I have further shown that the contraction takes place at both poles, as well as with both currents, and it consists in a steady and gradual drawing together of the muscular substance without *any immediate* relaxation; in this respect involuntary muscles act very differently from voluntary muscles, which—except when they are greatly fatigued—relax immediately after contraction. The effect of the contraction is a diminution in size of the organ that is acted on. Now, as the blood-vessels contain involuntary muscular fibre, their diameter must be diminished by electrization, and in this way congestion may be relieved.

I have found out in my researches—what I believe has not been before observed—that the positive pole has a stronger contracting influence on involuntary muscles than the negative pole. This differential action applies to both currents, and, so far as I can judge, without regard to the direction of the current. This fact, taken in relation with the fact that the chemical effect of the positive pole is less active than that of the negative, would explain, in part, the fact which I think I have observed,—that the positive pole is the more efficacious in treating spinal congestion. The influence of current-direction in the treatment of this and of other affections of the cord has been overdrawn. It may, indeed, be doubted, and for myself I do most seriously doubt, whether there is any such differential action between the ascending and descending currents as has been claimed. Without arguing the details of the subject here, I may say that all observation accords with physics and physiology in making the *polar* action more prominent than the effect of current-direction.

(To be continued.)

A CASE OF HYDROPHOBIA.

BY JOHN KNIGHT, M.D.

AT 9.30 P.M., October 12, 1873, I was called to see Henry W., aged 11 years. The messenger supposed him to be suffering from hydrophobia.

I found the patient sitting on a chair by the stove, complaining of headache, inability to spit, feeling of constriction of throat and chest. Pupils widely dilated. Pulse wavering, and so rapid that I was not able to count it. Skin hot and dry. Tongue parched, and much swollen, of a bluish color, showing a high state of congestion. I found a punctured wound on the inner surface of upper lip opened, the boy having been bitten in the lip and nose. The latter wound had healed kindly, and showed no signs of any injury. He made frequent attempts to clear his throat, making a noise as any one would who had a fish-bone in the throat,—which the bystanders called barking,—followed by ineffectual efforts to spit, there being no saliva about his mouth; then convulsive action of muscles with tendency to opisthotonos, but not hard enough to throw him off his chair. He had not swallowed anything since the previous morning at breakfast, but had constant thirst, and asked for a drink. I told his mother to get him a glass of water, that I might see what effect it would have. While she was getting the water off a table close by, he rose up, seeming to prepare himself for a struggle. As she came towards him he made a bound, caught the glass with both hands, forced it to his mouth, got a mouthful, but was unable to swallow one drop; it all flowed out of his mouth, and he went into a convulsion. That effort to get a drink was the most desperate I ever saw a human being make to accomplish any purpose. He not being able to swallow, I concluded to quiet him by injections; prepared an enema of starch-water containing one-half drachm of chloral, with one grain morph. sulph. When I would touch him with the nozzle of the syringe he would have a convulsion. After several attempts, I succeeded in throwing into his rectum about three-fourths of my solution, which had a very happy effect on the paroxysms, they being neither so frequent nor so hard; stopped all clearing of his throat and efforts at spitting. While the effect of the enema was at its height, he was able to take two swallows of water,—the first he had drunk for forty hours,—and in a few minutes he took two or three swallows more. Sometimes the sight of water would excite a convulsion, and again, being merely repulsive to him, he would turn his back, and make a motion to put it away, with his hands.

At 2 o'clock A.M., the convulsions having returned in force and frequency, I repeated the enema, with the same quantity of chloral and one-half grain of morphia, then went home. Visited him early in the morning; found he had died about 5 o'clock, in a convulsion. His mother informed me he had lain quiet until the convulsion in which he died.

This boy was bitten by a rabid dog on the 13th of September, at 8 A.M.; at 4 P.M. was admitted into one of our hospitals, where the opinion was given that, it being only a trifling affair, and several hours having elapsed since the biting, it was not necessary to do anything but watch the case.

On the 15th he escaped from the institution and went home, where no attention was given to his case until I saw him, the night before his death. Upon closely questioning his mother, a most ignorant Irishwoman, I find she saw nothing amiss with her boy until the night of the 9th of October,—twenty-six days after the biting. He was restless, unable to sleep well. Friday he was fretful and quarrelsome, and at night rested worse than on the preceding one. On Saturday he ate a little break-

fast,—his last; was cross, uneasy; kept moving about from place to place; quarrelled with the other children; slept none at night; had his first convulsion on Sunday morning; kept moving all day from place to place.

My main object in placing this case before the profession is to call their attention to the fact that it is better, when called to such a case, to use every known means to prevent the system being poisoned by the virus, though several hours or days may have elapsed since the injury.

The period of incubation in this case being prolonged to twenty-six days shows that the virus was not taken up by the absorbents for several days after the biting.

FOX CHASE, 23d WARD, PHILA.

THE DISTRIBUTION OF NERVES IN REFERENCE TO NEUROTOMY.

BY HENRY C. CHAPMAN, M.D.

EVERY student of physiology will follow up with interest a case of neurotomy, both as regards its therapeutic effects, and in reference to its offering a test for our knowledge of nerve-distribution. It was with great pleasure, therefore, that I began to read an article on "Neurotomy" which appeared in the *Medical Times* for December 6. Candor compels me to admit, with great respect, however, that certain statements soon excited in me feelings of astonishment, and that I finished the article with the impression that if Dr. Mitchell was right, all the anatomists were wrong. Dr. Mitchell says, "Take, for instance, Flower's Atlas, or most of the anatomies, and you will see the median innervates this area, and the ulnar that, and so on, while in truth *this surface anatomy is a fiction*, and has to be studied anew, by closer dissections and by utilizing such nerve-sections as are made in man." As proofs of this extraordinary assertion, the doctor mentions several cases in which the radial, ulnar, and median nerves were involved. I will therefore give as brief an account as possible of the distribution of these nerves, as accepted by anatomists, and trust that the diagram, kindly furnished by Dr. Leidy, will sufficiently illustrate the subject. I will try to show, so far from the surface anatomy being a "fiction," that, not only in its general features, but in detail, it has been made out correctly for years, and that the accepted anatomy perfectly explains the phenomena which seem to have caused perplexity to Dr. Mitchell.

By looking at Fig. 1, we see that the back of the hand is supplied by the dorsal digitals of the radial, dorsalis ulnaris, and their anastomosing branches; the thumb and the index-finger, by a digital of the radial; the radial side of the middle finger, by a digital of the radial; the ulnar side of the ring-finger, by the digitals of the dorsalis ulnaris; while the adjacent borders of the middle and ring fingers are supplied by digitals coming from an interlacing of the radial and dorsalis ulnaris;* the little

* These nerve-filaments supplying the adjacent borders of the middle and ring fingers are subject to variation.

finger is supplied by the digitals of the dorsalis ulnaris.*

In nature these digital nerves extend through anastomotic filaments to the last phalanx; in Fig. 1, however, they are represented as terminating rather abruptly in about the middle of the finger: this has been done purposely, with the object of bringing out distinctly the important fact that the

ends of the fingers are supplied by the dorsal rami of the palmar digitals of the median and ulnar nerves, as well as by the digitals of the radialis and dorsalis ulnaris.

By looking at Fig. 2, representing the index-

dorsal ramus of the palmar digital of the median,

which anastomoses with the filaments coming from the interlacing of the radialis and dorsalis ulnaris, on its ulnar side by the dorsal ramus of the palmar digital of the ulnar, which anastomoses with the digital of the dorsalis ulnaris; the end of the little finger is supplied by the dorsal rami of the palmar digitals of the ulnaris, which anastomoses with the digitals of the dorsalis ulnaris. It is to be understood, also, that the nerves supplying the radial and ulnar borders in each finger intercommunicate through anastomotic filaments. Such is substantially the account given of the usual distribution of the radial, ulnar, and median nerves in the works of Leidy, Quain and Sharpey, Holden, Gray, Hirschfeld and Leveillé, etc., and the correctness of which, according to my knowledge, has never been questioned by an anatomist of reputation. According to Dr. Mitchell, however, there has been a conflict of opinion among the clinicians and physiologists, and "the anatomists are in part responsible for the clinical difficulty. Take, for instance, Flower's Atlas or most of the anatomies." We are surprised at any one referring to Prof. Flower's Atlas as an authority on this particular point, since it is admitted in the preface to that work "that the plates are only diagrams or plans, and that in reducing to a plane surface objects which in reality are superimposed at various distances, and which sometimes cross one another, their mutual relations and proportions must often be disarranged." While therefore the atlas of the eminent anatomist Prof. Flower may serve very well for its purpose, its plan of construction necessarily renders it almost useless in reference to the distribution of the nerves as regards a question of neurotomy. Further, in support of statements concerning the anatomy of the nervous system, it will not suffice to quote one English authority and refer vaguely to "most of the anatomies."

Any one at all conversant with scientific literature well knows that a thorough investigation of any subject demands the careful study of many authors. As regards biology, of the German writers, especially, Prof. Huxley says, "Ask the man who is investigating any question profoundly and thoroughly, be it historical, philosophical, philological, physical, literary, or theological, who is trying to make himself master of any abstract subject (except perhaps political economy and geology, both of which are intensely Anglican sciences), whether he is not compelled to read half a dozen times as many German as English books." In reference to this particular anatomical question, however, to do justice to the English anatomists, we call attention again to the excellent works of Gray, Holden, Quain and Sharpey, which are readily accessible to every American student. Imperfect knowledge of foreign languages is, therefore, no excuse for ignorance on the subject of anatomy. Supposing that our brief exposition of the nervous distribution in the hand is correct, let us now examine the phenomena noticed by Dr. Mitchell, and see if they do not entirely confirm what has long been known of the nervous system of the upper extremity. In speaking of Dr. Maury's very inter-

* To avoid confusion, the external and internal cutaneous nerves are not represented in Fig. 1.

esting case, the division of the brachial plexus for a painful cutaneous affection, Dr. Mitchell says, "At first the posterior and inner cords were cut, and the patient was allowed to become free of the effects of the ether. To my surprise, he still had touch-sense in the palm and dorsal surface of the hand, forearm, and arm, and on the inner face of the arm." I do not understand why there should have been surprise that "the palm and dorsal surface of the hand, forearm, and arm" should have retained touch-sense, so long as the external cord remained uncut, since the external cord forms part of the median and the external cutaneous, the very nerves supplying the parts which retained the touch-sense. Indeed, I should have been surprised had it been otherwise. As regards the "inner surface of the arm," the influence of the intercosto-humeral must be remembered. Dr. Mitchell says, "Sometimes the median, for example, innervates the palmar face of the thumb, the index-, and half of the second finger, sometimes extends over the whole face of the latter, and very often reaches the line given in Flower's plates, which carry it up to the middle of the face of the third finger." So far from this being "sometimes" and "very often" the case, it is almost invariably the arrangement, not only in man, but in quadrupeds, carnivora, and in pentadactyles generally. This general agreement of nerve-distribution in five-fingered animals is very important, since the wider the field of our observation the more reliable will be our conclusions.

I do not think it necessary to give a diagram of this arrangement, since it may be seen in any anatomy. In reference to the median nerve, it is an interesting fact that in man it has been observed to pass through the internal condyle of the humerus. This abnormal arrangement is quite normal in felines and some other mammals,—an illustration of the general law that what is abnormal in man is often normal in lower animals.

To continue: Dr. Mitchell, in speaking of variations, observes, "The radial nerve has been cut, and has left in one case so large a degree of feeling on the dorsal surface of the hand that neither the patient nor the physician could perceive that there was any loss at all." Is there any cause of astonishment here, when one remembers that, supposing the radial was cut, the back of the hand would still be supplied by branches of the external and internal cutaneous dorsalis ulnaris and the interosseous nerves?

According to Dr. Mitchell, "a year ago, if a surgeon had been asked to cut a nerve to relieve a local injury on the extremity of the dorsum of the index-finger, he would, without doubt, have cut the radial; and yet, as we now know, the median may have been equally or more to blame." The least I can say of such a surgeon is, that he would have been pitifully ignorant of elementary anatomy.

Once more, and I cease to tire the reader with details familiar to every anatomist. "Doubts of like nature would arise if the cause to be quarantined by nerve-section lay in the third finger, because sometimes that part is fed by the median, sometimes by the ulnar, at times by both." The

third finger is always supplied by the digital branches of the dorsal rami of the median and ulnar, the digitals of the dorsalis ulnaris, and almost always by filaments which come from the interlacing of the radialis and dorsalis ulnaris. We repeat, this last disposition of these interlacing filaments is subject to variation. Personally, I cannot understand why the phenomena noticed by Dr. Mitchell caused confusion; indeed, I must say that the perplexities of our clinical and physiological friends in reference to this subject remind me of what the celebrated metaphysician Berkeley says of his favorite study, "We have first raised a dust, and then complain we cannot see." I do not wish to leave the reader with the impression that I consider the structure of the nervous system has been exhaustively studied. On the contrary, as Prof. Henle observes in his classical work, "*Handbuch der systematischen Anatomie des Menschen*," p. 500, "Superficial physiological experience confirms the result of anatomical investigation. Modern surgical transactions have still brought to light facts upon the nerve-commissures which prove that the course of the fibres is not so simple, and our knowledge of the same is not finished. However, for our object this question may remain unsettled, for Richet's observation alone suffices to show that the fingers do not receive their sensible fibres solely from branches which extend straight to them."*

While I admit that no doubt, from time to time, there will be additions to our knowledge, I cannot endorse any such sweeping statement as "this whole surface anatomy is a fiction, and has to be studied anew." As regards learning the distribution of nerves, Dr. Mitchell seems to consider that cold, pressure, and electricity serve as means of investigation. It is with very great diffidence that I offer any criticism to these statements, as well as those above mentioned, of such an esteemed physiologist as Dr. Mitchell. I must say, however, that it appears to me, admitting the free anastomoses of nerves, that any result based on such a mode of experimentation would be very unreliable, and that inflicting pain lets in an abnormal condition, which will further vitiate, more or less, the conclusion. No subject illustrates better than the pathology of the nervous system not only the importance, but also the absolute necessity, of the thorough study of anatomy and physiology. Consider the vast amount of pathological data that remained for years almost useless on account of the healthy condition of the nervous system being so little understood. It appears to me that the medical profession, in their studies, begin where they should end: studying disease before health. In every other science the study of the normal precedes that of the abnormal,—the simple that of the complex. Why, therefore, in the most difficult of

* "Die oberflächlich physiologische Erfahrung bestätigt das Resultat der anatomischen Untersuchung. Doch haben die neuerlichen chirurgischen Behandlungen über die Nerven thatsachen zu Tage gefordert, welche beweisen das der Faserlang nicht so einfach und unsere Kenntniss desselben noch nicht abgeschlossen ist." After noticing the observations of Beclard, Paget, Schiff, Laugier, Houell, Richet, in reference to the uniting of nerves after division, Prof. Henle continues at p. 501, "Indess darf für unseren Zweck diese Frage unerledigt bleiben, da Richet's Beobachtung allein genügt um zu zeigen dass die Finger ihren sensibeln Fasern nicht lediglich aus den Aesten empfangen welche sich geraden Wegs zu ihnen erstrecken."

all studies should they use a method not found successful in the cultivation of the sciences?—in the words of one of the deepest thinkers of this century, the late Mr. Buckle, "physiology is the basis of pathology, and the laws of disease are to be raised not from the phenomena presented in disease, but from those presented in health: in other words, pathology should be investigated deductively rather than inductively; and morbid anatomy and clinical observations may verify the conclusions of science, but can never supply the means of creating the science itself."

CURIOSITIES OF COUGH.

Reported to the Medical Library and Journal Association, December 12, 1873,

BY L. ELSBERG, M.D.,

Professor of Laryngoscopy and Diseases of the Throat in the University of New York.

(Continued from page 246.)

III.—July 14, 1873.—Miss H. R., of Philadelphia, æt. 18, of healthy family, though small and delicate herself, weighing only ninety-three pounds, "got a cold in the head" during November, 1872; it lasted two or three weeks, and ended with a curious little vocal hack of a cough that has remained ever since. Except during sleep, she has this peculiar cough—if it is to be called a cough—every two or three seconds, without cessation, unless engaged in conversation or swallowing, when she can suppress it for about seven or eight seconds; it always occurs at least ten or twelve times every minute. It is an expiratory sound like the "ha" of people when they want to express derision. By its frequency breathing is quickened, as the patient always takes an inspiration, and occasionally two inspirations and one expiration, between every two coughs; otherwise nothing abnormal can be detected about the respiration. The pulse is 120, weak and nervous; temperature (taken in the mouth) 100.3°. She complains of pain in the back, especially on sitting for any length of time; and, on examination, three or four spots sensitive to slight pressure were found along the spine, the most acutely painful being in the lower lumbar region. This back-ache she has had, however, for many years before the vocal hack came on. She also has had melanotic discoloration in small spots on both her hands and feet since early childhood. She does not sleep well, waking up several times during the night. Her appetite is exceedingly poor; bowels inclined to constipation. Menstruation has always been regular and normal. There is no organic disease discernible in either lungs or heart; the upper air-passages show anæmia and some little congestion. With the laryngoscope the arytenoid cartilages are seen to approximate with a rapid spasmodic movement which marked the peculiar vocal phenomenon; and with the hand placed upon the abdomen, a synchronous jerking contraction of the diaphragm can be felt. Electrical reactions carefully investigated—with the advice, and on one occasion the personal aid, of Dr. Neftel—threw no further light upon the case. To prevent, if possible, the continuance of any possible morbid pressure, I consulted Dr. E. Banning, who applied one of his braces, which the patient continues to wear every day with great benefit to her back, but no influence upon the peculiar cough.

Although I do not intend to lengthen this recital of curious cases by detailed description of the treatment pursued, I cannot refrain from adding

that after the failure of internal medication by sedatives, antispasmodics, and narcotics, and of electricity, both faradaic and galvanic, singly and combined, applied internally and externally in various ways, this strange cough has been cured by local treatment of the slightly-congested faucial and laryngeal mucous membrane with sol. iodine and hypodermic and hypophlegmymenic injections of morphine.

(To be continued.)

TRANSLATIONS.

RENAL TUBE-CASTS IN ICTERUS.

IN the examination of a case of simple icterus catarrhalis in a young man of previous good health, Professor Nothnagel (*Deutsches Archiv für Klinische Medicin*, October, 1873) discovered in the urine a quantity of perfect casts; and as the subsequent fading of the jaundice from the skin, under an entirely expectant treatment, was attended by a diminution and final disappearance of the casts, some pathological connection between the two phenomena was naturally supposed to exist. Since that time he has investigated the subject, and from the personal examination of a large number of cases of icterus draws the following conclusion: "*Whenever the jaundice becomes comparatively intense, independently of its anatomical cause, casts appear*;" to which he adds, "*if the urine at the same time contained the biliary acids*."

Leaving out of the question cases complicated with renal disease, the fact that casts could appear in some cases of icterus is already known, but was always considered as an accidental appearance, or at the most was described as an occasional symptom of acute yellow atrophy of the liver. For instance, Bamberger does not refer to it at all. Frerichs says that "here and there a small amount of albumen would be temporarily found," but does not mention casts. Only Leyden, in comparing icterus gravis and acute hepatic atrophy with the production of the bile-acids, observes, "The urine, also, in both cases shows the same alteration: it contains albumen and casts." No one has suspected casts in other varieties of icterus.

He states that these abnormal elements can be proved to exist in icterode urine, *as a rule*, whenever the jaundice becomes intense. He therefore wishes to class this with the more constant symptoms of icterus, such as pruritus. This has escaped notice hitherto because the urine of jaundice-patients is rarely carefully examined, especially if there is no albumen present; even if it were, the casts are sometimes in such small numbers that they would escape ordinary observation.

The cases in which casts were found were principally icterus catarrhalis; also in jaundice following gall-stone colic, or consequent upon compression of the common bile-duct by a neoplasm; in pyæmia, in a case where closure of the mouth of the gall-bladder existed; and, finally, in a case of bilious pneumonia. In all of these the jaundice was of high grade, and the skin intensely yellow. The urine always gave a positive bile-pigment reaction; acid; specific gravity 1.010 to 1.020; deposited urates on cooling, and became entirely clear. In several cases, especially that of pyæmia, the presence of the biliary acids was established by Pettenkofer's test.

In the cases where casts could not be found, the icterus was slight; either it had never been of a high grade, or was already declining when the patient came under observation.

The quantity of the casts varies, in some cases being numerous, in others requiring from four to six preparations to discover two to three casts. This shows that a negative result should not lead us to form a hasty conclusion. The variation seems to be in proportion to the extent of the icterus; the more marked this, the more numerous the casts. In the great majority of cases they were hyaline, and occasionally contained a few, or sometimes numerous, small, glistening, yellow granules (fat?); or there rested upon them one or more bright-yellow epithelial cells from the tubuli, or a few white blood-cells likewise tinged with yellow. Exceptionally, these were all present. Not so frequently as the hyaline, but also not rarely, unmistakable epithelial casts appeared, consisting of closely-crowded kidney-epithelium, also stained. In most of these a hyaline base could be recognized. Only very exceptionally were casts seen to which the name "fibrinous" could be applied; these were colored, and bore, here and there, epithelial or white blood cells. There were also found large bladder-cells, leucocytes, and kidney-epithelium unconnected with the casts. An important point is noticed in reference to the casts: although the urine and all the other elements were strongly tinged with the bile-pigment, *the hyaline casts were always entirely colorless.*

In about two-thirds of the cases there was no response to the usual test for albumen. To ascertain if it was present in some modification, a quantity of the urine was largely diluted, treated with alcohol, and the precipitate incinerated on platinum; there was no swelling of the substance, but it steadily diminished under the increased temperature: the conclusion may then be adopted that no albumen whatever was present. In some cases this absence was in marked contrast with the number of casts found.

The occurrence of casts without albuminuria, although always a rare and interesting fact, has been before noticed. Griesinger and Rosenstein have reported such cases; and Key saw hyaline casts when the kidneys were entirely normal.

That when these casts occur in jaundice they are connected with it, is evident. Although no previous examinations were made, yet the manifest relation existing between the intensity of the icterus and the number of these abnormal elements, the fact that both disappeared under an indifferent treatment, the patient's (icterus catarrhalis) previous good health, the absence of albuminuria—all lead to one conclusion, and exclude the supposition of co-existing kidney-disease. A febrile origin cannot be urged in explanation, because in some cases fever was entirely wanting.

The biliary acids then suggest themselves as the exciting cause of this abnormality. How they produce the changes in the kidney or cause the appearance of the casts need not be discussed, but that they will do so may be accepted as a fact from the experiments of Leyden, who, having injected a considerable quantity of these acids into the veins in several experiments, observed albumen and casts in the urine.

That there is a direct dependence of the constant appearance of tube-casts in intense icterus upon the bile-acids is evident, but as to the details of this connection no hypothesis is ventured.

FRANK WOODBURY, M.D.

KOUMYS (*The Irish Hospital Gazette*, December 15, 1873).—An establishment has been opened near Vienna for the "koumys cure" of lung-diseases, or the treatment of such diseases by the use of mare's milk in the process of fermentation. The cases which have proved most suited to this treatment are those of chronic phthisis, when there is great wasting of the body, and

when the indication is to increase the weight and general strength of the patient. In such cases, it is said, koumys seems to work wonders, increasing the quantity of urine, lessening the night-sweats and the tendency to hæmoptysis, and changing the type of the disease from the more acute to the more chronic form. The quantity for an adult to begin with is two half-bottles per diem, increasing this dose by a half-bottle each day until the measure of three or four bottles is reached. The patient should live almost exclusively on koumys.

ALBUMINURIA AS A SYMPTOM OF MENINGITIS (*Medical Press and Circular*).—Professor Rosenstein has noticed the coincidence of albuminuria with meningitis. The analysis of their urine demonstrates in nearly all patients, whether old or young, attacked with meningitis, the presence of albumen in the early days of the cerebral affection; and in a considerable number of these cases there are found at the same time, among the products of the renal secretion, epithelial cells, blood-globules, and fibrinous casts, exactly the same as in Bright's disease. The lesions discovered by post-mortem examination of the kidneys are likewise similar to those of albuminous nephritis. The kidneys are increased in size, the hypertrophy being chiefly in the cortical substance; the renal tissue is markedly injected, the glomerulæ are gorged with blood, and there are extravasations of blood into the urinary tubules. Professor Rosenstein attributes these lesions to troubles in the circulation, due to functional alteration of the vasomotor nerve-filaments. This fact is likely to be of considerable value in diagnosis.—*Lyon Méd.*

PEPSINOMANIA (*The British Medical Journal*).—We learn from a report in the *Chemist and Druggist* that Dr. Schacht, a councillor and recently president of the Apotheker-Verein, lately read a paper on *Pepsin and Schering's Pepsin Essence*. He showed that pepsin only dissolves albumen in the presence of free acid, but that a given small quantity of pepsin will effect the solution of any given larger quantity of fibrin, on the same principle as a small quantity of sulphuric acid acting upon alcohol will continue to produce ether. Further, he showed that when the limits of its dissolving capacity are attained, yet by dilution with water and further addition of acid more solution will be effected. He also maintained that a stomach had never been found without pepsin, that the natural pepsin was never entirely destroyed by the process of digestion. From this he concluded that the administration of the artificially-obtained product could only be a work of supererogation. It is evident, also, from these premises, that the value of a pepsin cannot be estimated by the quantity of fibrin which it will dissolve, but by the time it occupies in dissolving it. Dr. Schacht's experiments also went to prove that wine or alcohol were the worst possible vehicles for the administration of pepsin. It was probable that the tannin of wine almost entirely hindered the catalytic action of the pepsin. Some experiments were shown to prove that it is much more effective if dissolved in water. Of course, in either case hydrochloric acid is necessary. Dr. Schacht chastised the "pepsinomania" in England, and referred to such preparations as Mr. Lorimer's sauce, which, however, was, he thought, preferable to the pepsin essences or wines. The speaker concluded that the administration of pepsin or any of its preparations was altogether unscientific, on the ground that no stomach had yet been observed in which the remedy was already absent.

SPONGE-TENTS (*The British Medical Journal*, November 29, 1873).—Mr. Lawson Tait believes that by soaking sponge-tents in oil of cloves they will be made more agreeable to the patients, and at the same time there will be much less risk of their causing septicæmia and peritonitis.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

SATURDAY, JANUARY 24, 1874.

EDITORIAL.

OUR CRIMINAL INSANE.

Governor Hartranft deserves the thanks of the friends of humanity and justice, as well as of the lovers of the fair fame of Pennsylvania, for his well-meant and cordial appeal to the Legislature in behalf of the so-called "criminal insane." We regret that he did not call their attention to a yet wider field: to the equally pressing claims of the far more numerous class of the insane poor, who are incarcerated in the poor-houses, as well as the prisons, of the State. But we cannot resist the conviction that this portion of his message was written under some misapprehension of the actual state of the case, even in respect to the particular class referred to. It is with unfeigned diffidence that we venture, and with much regret that we feel constrained, even in appearance, to controvert or criticise any of his positions. But the claims of truth and right are paramount, and we are sure that no one will be more ready than Governor Hartranft to correct any mistakes into which he may have been led by inaccurate or partial representations.

We doubt not that the State hospitals for the insane deserve much commendation, and are doing a good work for the State in many respects. But the "plea" in behalf of the insane poor of this commonwealth recently put forth by the Board of Public Charities,* and which will be embodied in

* As the "Plea" may not be seen by some of our readers, the following extracts are appended to show the importance of the subject to which we

their annual report to the Legislature, has, we think, by its array of facts, and by the concurrent testimony of the judges of our courts and the inspectors and wardens of our penitentiaries, put it beyond all question that those hospitals, and particularly that at Harrisburg, have not been accomplishing, to the extent that might reasonably be required of them, the purposes for which they were by the State designed,—the reception, care, and treatment of the insane poor. Hundreds upon hundreds of these are pining in the poor-houses and prisons of the commonwealth, while one of these hospitals has had, and still has, from one-half to two-thirds of its inmates *paying patients*. The county authorities are not invited

have to-day allotted so much space. Evidently some of the missionaries sent by our Christian philanthropists to Barbary and Algiers should be recalled for the benefit of the heathen in central Pennsylvania.

"In February last a visit was paid this almshouse, and an insane inmate was seen,—a young woman over twenty years of age, whose whole dress consisted of a thin chemise with short sleeves, a single skirt, and a pair of shoes. When brought before the visitors, a borrowed cloak was thrown over her shoulders. She was blue with cold, and utterly filthy in person. Her cell had the appearance of having undergone a recent hasty washing, but was pervaded with an odor loathsome in the extreme. On the day of this visit the thermometer fell to 14 degrees.

"In March another visit was paid to the institution by several gentlemen in a body. Only one portion of the building was visited, which is supposed to be devoted exclusively to women. In one cell was a young woman,—the one already referred to. Her cell was without any furniture whatever, her bed consisted of one blanket, her clothing a ragged chemise open to her waist, and one scanty skirt and a pair of shoes. She was indescribably unclean, and alive with vermin. Her cell reeked with a sickening odor, the result of a total absence of all conveniences for cleanliness. She shivered with cold while in the presence of her visitors; the thermometer standing, at the time, several degrees below the freezing-point.

"Opposite to the cell, which we have very faintly described, was another. The short day had already faded into dusk, and as the light was thrown through the little aperture in the door, it fell upon two wretched women, both of whom were absolutely without a single garment to cover them. One of the poor creatures sat crouching in the corner with a small blanket drawn across her shoulders, while the other was crawling on all fours on the floor, without even this poor apology for any remnant of human decency! There was not a particle of furniture in the cell; and there, on this wintry March night, in an atmosphere which the witnesses declare to have been utterly horrible, were these two human beings, brought down far below the level of our domestic brutes.

* * * * *

"Insane totally neglected, morally, physically, and medically; less attention is given to them than would be given to the lowest animals; four are incapable of self-care, confined in filthy cells; one, a female, has great neighborhood notoriety from sad incidents connected with her history. Known as an intelligent, esteemed, and attractive young lady, the daughter of a well-known inhabitant of the neighborhood, she fell a victim to the arts of the seducer. Insanity is alleged to have been caused by her disappointment. This occurred twenty-one years ago. The sad case is rendered still more painful by her present forlorn condition. A bed of straw, upon a damp, dirty floor, into which the external light can find no entrance, is the only furniture. A seat, a chair or a bench, has apparently never been furnished; the consequence of which is that the muscles of the lower extremities, from the cramped position in which she was always found, have become permanently contracted, so that the only movement of which she is capable is one similar to that of a frog.

* * * * *

"Twenty-two insane; twelve are kept in close confinement, some in chains; one always chained to the ceiling to prevent him from tearing his clothes; some entirely nude; at least six with straw litters; not one of the twelve was ever removed into the open air. All confined in apartments opposite each other, a narrow corridor extending between them. The effect of this close proximity was to make the day and night hideous with the distressing shrieks and yells of the wretched and maltreated madmen."

and encouraged to send their insane to the hospital, except a few of the more recent cases. Indeed, it is understood, as we are informed, that the hospital at Harrisburg will receive no cases from the county authorities if they have had the malady beyond six months. The judges of the courts are deterred and debarred from sending those acquitted of crime on the ground of insanity, especially those of the more dangerous class, or those acquitted upon the charge of the graver offences, or whose disease is not "speedily curable," because the hospitals are already crowded (crowded, observe, chiefly with "paying patients"), and because the hospital authorities can summarily remand any of the less curable cases to prison. The fact is that the anomalous power just referred to, given to the hospital authorities by the law of 1861, has resulted in defeating, to a very large extent, the wise and beneficial purposes and provisions of the law of 1845, under which the first State lunatic hospital was established,—established for the very ends and objects which appear to have been disregarded in its administration. We make these statements with sincere reluctance, and not because we have any emotion of unkindness towards any individual connected with its management. On the contrary, we are quite sure that the medical superintendent is an amiable and estimable gentleman, and a skilful physician in his chosen department of medicine, and we know that the trustees are highly honorable and conscientious; but we make them because we feel keenly the grievous wrongs of the poor, helpless unfortunates, in whose behalf we would join in the earnest memorials of the judges of the courts and other eminent citizens, lay and professional.

The "plea" of the Board of Public Charities is a document of considerable length, and has just been issued from the press. We presume that Governor Hartranft had not read it when his message was prepared. We think that no one can read it with candid consideration without being convinced that the system of management of our State hospitals for the insane, in respect to the reception and retention of patients, and the provisions of our laws for the care and treatment of this class of sufferers in general, require to be thoroughly revised and reformed.

As to the memorial of the committee of the Medical Society of Pennsylvania, signed by the chairman, the superintendent of the Harrisburg lunatic hospital, one is not surprised, considering the respectable source from which it emanates, that Governor Hartranft should have presumed it to be worthy of unhesitating confidence and consideration, and should have been led to a quasi-adoption

of its suggestions without a careful scrutiny of their bearing and character. But we trust that, before acting upon the subject, the Legislature, as well as the Executive, will give this "Memorial" a thorough scanning and analysis.

It proposes, at the outset,—and so Governor Hartranft apparently understood it,—to consider the *general case* of the "Criminal Insane;" and yet it makes at last the lame and impotent conclusion of a mere suggestion of legislative provision for the better care and treatment of only a small fraction of these: viz., "insane convicts," endorsing, with respect to this comparatively insignificant portion, the resolutions adopted by the Association of Medical Superintendents at Baltimore. This is the only action, the only legislative reform, it proposes. But as the laws of this State, and the practice under them, now stand, the claims of insane convicts to relief, as compared with those of other classes of "insane criminals," so called,—whether we consider their respective numbers or the hardship or injustice of their present treatment,—are as nothing. It is not the score or so of insane convicts, but it is the multitude of those who, in a state of insanity, have committed, or are liable to commit, what are called crimes, but who are morally irresponsible for their acts,—it is these who are suffering unspeakable wrong, and whose wretched condition demands the immediate attention of the Legislature. The "Memorial" declares that for these last "the law provides full and adequate means of relief; that they shall be placed in hospitals built and arranged for their care and treatment until they should be restored to their sound minds." It then coolly assumes that these "means" are effectual, that all this class are actually thus taken care of; and it proposes no legislation, no measure of enlargement or improvement of the "full and adequate means of relief" thus provided for them. Would not every unguarded and simple reader of this "Memorial," considering, as we have said, the respectable source from which it comes, presume that all this class of insane among us were duly cared for in our State hospitals? Would he believe, would he imagine it possible, that there should be at this moment, in the commonwealth of Pennsylvania, numbers of this class of irresponsible "insane criminals" raving and rotting in the cells of our prisons and the dungeons of our poor-houses, and that our criminal judges and magistrates should feel obliged from day to day to commit such helpless sufferers to a hopeless incarceration in such abodes of misery? Yet such is the fact; and it is one of the foulest blots upon the honor of our State. Does any one doubt it?

Let him read the "plea" of the Board of Public Charities, and his doubts will be removed.

And now, whose fault is it? Is it the fault of the judges? Is it the fault of the hospitals? Is it the fault of the law? One of these, it would seem, it must be, if there is any fault at all. As to the judges, read their statement and memorial, contained in the "plea," and no doubt they will be exonerated. The fault, then, must be either with the hospitals or with the law, and then, in either case, it comes back upon the hospital authorities; for the present state of the laws upon which the evil might be charged has been brought about by their procurement; and they have never asked any amendment of the law in this regard, but rather have obstructed any such amendment; just as this "Memorial," which betrays the inspiration of a hospital superintendent, makes not the slightest suggestion of any change of the law in relation to this subject, but expressly declares its provisions to be "full and adequate for the relief" of this class of lunatics. We leave to others to characterize as it deserves a "Memorial" professedly put forth in the interest of humanity and in behalf of this particular class of sufferers, but which coolly abandons the helpless and innocent to their present fate, under the "full and adequate provisions" of the law,—a fate and a law which some of its authors have had a principal hand in securing,—and then covering its retreat with a lame suggestion of some doubtful relief for a dozen or two of "insane convicts." But meanwhile it cannot be too emphatically asserted and insisted on that, next to adequate provision for the "insane poor" in general, the great point to be urged upon the attention of the Legislature is, not the case of "insane convicts," but that of those innocent lunatics who, by an abuse of words rather singular, though easily explained, are commonly called "*the criminal insane*."

We follow this "Memorial" to another point, of less importance. Although, in the end, it seems obliged to admit that some relief should be provided for "insane convicts," it takes pains to blacken their character as much as possible on the way, and to arouse as strong a prejudice as possible against their claims. Even the horrible doctrine that insanity may be regarded as a part of their penalty is coolly endorsed. "They have every reason"—such are its words—"to look upon the insanity as a part of the penalty which their crimes have brought upon them, and cannot complain if society should so regard it and act accordingly." But by whose sentence or act is the penalty inflicted? What does the "Memorial"

take society to be composed of? of fatalists or savages? It may be true that the poor lunatics, who receive from the hand of Providence no more than a just punishment for their crimes, have no right to complain if society regards and treats them accordingly; but reason, justice, humanity, decency, have a right to complain, and to set the seal of their emphatic condemnation on such an infamous, not to say blasphemous, suggestion,—a suggestion which, so far as it possesses any plausibility, has been anticipated, analyzed, and demolished in the "plea" of the Board of Public Charities.

Having described, and very properly described, the first class of so-called "insane criminals," the irresponsible or innocent class, the "Memorial" adds, "The other class consists of those who, having led a life of crime, having been at war with society all their lives, and being in constant violation of the laws of God and man, are at some point in their career arrested by the strong arm of the law and confined in prison. After a time they may become insane, and need care and treatment." Between these two classes it recognizes no gradation, no intermediate cases: all "insane convicts" are regarded as coming under this last description. Now, that there may be some of this character is not to be denied. But that, even of "insane convicts" as a class, it is a false and slanderous description, must be evident to any one who will read the reports of the inspectors and wardens of penitentiaries which are given in the "plea" of the Board of Public Charities. They show that by far the largest proportion of even "insane convicts" were probably insane before the commission of the acts and crimes for which they were convicted; and of the rest it is far from being true that, as a rule, it is the worst and most hardened criminals that are the most likely to become insane. As to their demeanor while under confinement or treatment, the testimony of those in charge of them is surprisingly to their advantage.

Dr. Compton, Superintendent of the State Lunatic Asylum of Mississippi, says, "My own experience with insane criminals" (the connection shows that he means "convicts") "leads me to feel rather charitably towards them."

Dr. Shaw, Superintendent of the General Hospital for the Insane, Middletown, Connecticut, says, "In practical experience, I have not found that 'insane convicts' are particularly objectionable in themselves. . . . Twelve insane convicts have been transferred from Wethersfield to Middletown; two of that number escaped, one of them having feigned insanity. Of the ten others, seven have been among

the most valuable farm-laborers,—harmless, industrious, and peaceable, and yet positively insane. They are generally liked by the patients, and are not more troublesome than others."

Dr. Earle, of Northampton, Massachusetts, says, "I would put the 'convict insane' in a separate institution, independent of all other institutions. I would *put in the same place* those who have been tried and acquitted of crime on the ground of insanity; then those incendiary and homicidal patients who never have been tried for crime. . . . Our most dangerous patients *are not convicts*, and have never been tried and acquitted of crime on the ground of insanity."

But, at all events (the "Memorial" urges), insane convicts are too bad to have a department provided for them in connection with any general hospital, because, in the first place, they will escape; for most of those who were sent to the Harrisburg hospital some years since soon made their escape.

It is true that, for some reason or other, they did manage to escape from the Harrisburg hospital. But have they escaped from the Dixmont hospital? Have they escaped from the Connecticut hospital? Have they escaped from the Mississippi, the Maine, or the Massachusetts hospitals? If really insane, it is not easy to see how they could make their escape permanently good, or, if they did, what great harm there would be in it; for apparently they must, in that case, be practically cured of their insanity, so as not to be capable of identification as insane persons. But, as a general rule, *they have not escaped*. The case at Harrisburg does not make the rule. Why they should be more likely to escape from the Harrisburg hospital than from any other, we leave for others to answer. If the prisoners escape through neglect of the keepers, the fact of the escape is not a good plea. It is a sound principle of reason that no man can plead his own wrong in support of his cause.

But, in the second place, it is urged that it is a hardship upon the other inmates of the hospital to admit "insane convicts" into association with them. The simple answer is, they might be admitted to a special and separate department in the hospital, without any such association; and this is really all that has been proposed.

In the third place, it is alleged that when "insane convicts have been admitted to general State hospitals it has been against the protest of the superintendents." Sometimes this has been so, and naturally enough; but it is by no means universally true. Dr. Compton, of Mississippi, in expressing his decided opposition to the doctrine that "under no

circumstances should 'insane convicts' be permitted to associate with other insane persons," added, with emphatic earnestness, "I would take them into my asylum rather than let them remain in the penitentiary or jail. In the absence of the proper provisions, I would take them out of the penitentiaries and jails and put them in my asylum." And such we understand to have been the almost universal sentiment of the superintendents of insane asylums in their late session at Baltimore, with the exception of some of those from Pennsylvania. An entirely separate provision for "insane convicts" was undoubtedly preferred as the best,—the ideal plan,—where such an establishment could be afforded; but, unhesitatingly, they would welcome these unfortunates to their asylums, rather than have them left incarcerated in prisons. In Pennsylvania almost alone have they been left to this hard fate; and here they have been so left because the State hospital "refused to receive them." "I would take them into my asylum," says Dr. Compton. "Let them rot in prison first," has been the voice from Harrisburg.

In the fourth place, it is alleged that New York has established a special hospital for "insane convicts," *on prison grounds*. Yes, but then most of the other classes of the "criminal insane"—the innocent and irresponsible—are consigned to the same hospital,—consigned to a prison-hospital,—a course contrary to all generous and humane sentiments, contrary to the strongly-expressed convictions of an apparent majority of the medical superintendents of Baltimore, contrary, even, to the suggestions of the "Memorial" itself; for, in the end, it concludes with a mere endorsement and reproduction of the resolutions of that convention, from which all approbation of the New York plan had been carefully eliminated. But it is not likely that New York would establish and support a separate hospital, with such full provision as is made for that at Auburn, simply and exclusively for her "insane convicts;" and that is what this "Memorial" seems to propose that Pennsylvania should do.

Finally, it is alleged that such separate hospitals have been established in Great Britain and Ireland. But there the number of "insane convicts" (being in some proportion to the population) is so great as to authorize the establishment of entirely separate hospitals for their treatment; and this would unquestionably be the best course for us if the State could reasonably afford it. Our "insane convicts" ought by all means to have provision made for their proper care and treatment. But, while the number is so small, we think the Board of Public Charities

has demonstrated that the cheapest, most feasible, and withal most reasonable and appropriate, arrangement for the State, is to provide, in the first place, a special department in connection with one of the State hospitals for the "criminal insane," so called, who are now languishing in our prisons and poor-houses; and then, with proper arrangements for such a degree of personal separation as may be thought best, to admit temporarily to this department "insane convicts" also, for treatment *while they remain insane*; temporarily, we say,—*i.e.*, until it is thought that the State should incur the expense of a fully-appointed hospital for their exclusive accommodation.

But if the proposed special hospital is to be placed on prison grounds,—to be made a department of a penitentiary,—then must we protest against sending to it the other classes of the "criminal insane," the innocent and irresponsible, who have never been tried for any crime, or, if tried, have been acquitted. We protest in their own name, in the name of their friends, in the name of the whole community, and in the name of reason and humanity itself. What we demand of the Legislature is that, first of all, for these the law should make "full and adequate provision" in a real and practical, and not a Pickwickian, sense,—a sense very different from that of this "Memorial,"—a sense which will not leave them, as that does, in the cells of our prisons and poor-houses, to languish out a hopeless existence of unspeakable and inconceivable horror. We would not have the "insane convicts" neglected—far from it; but we say again, it is for this other class, and not for "insane convicts" proper, that relief is first of all demanded of the Legislature.

And even if a special hospital for "insane convicts" exclusively be thought advisable, we see no reason in the world why it should be placed upon prison grounds rather than elsewhere, unless the State is to incur the expense of such a hospital for each and every prison; and if this is what is intended and proposed by the "Memorial," it does not appear that, after all, it would be a great improvement upon the present state of things. It might be some alleviation.

But again and again we implore the Legislature not to forget that other and far greater suffering class of the innocent victims of the law who are abusively called the "criminal insane;" and still less the yet larger class of the wretched *insane poor*,—now, with a grim mockery of humanity, consigned for safe-keeping to the poor-houses and prisons of the State.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

IN two numbers of your journal you have held up to professional condemnation the practice which has prevailed of having the names of the surgeons and physicians elected to the hospitals published in the newspapers. You aver that this gives to those gentlemen a great advantage over other medical men of equal skill and ability. This may be true; and yet I can hardly think the physicians and surgeons alluded to can be blamed for being thus announced at the time of election. Indeed, they could not easily prevent the ubiquitous reporter from publishing it. It is an item of news that belongs to him. But if after this first announcement it should be again published, either by themselves or by the managers with their consent or even their silent acquiescence, it would be advertising their skill, and would deserve your sharp and just criticism. If those gentlemen regard themselves as being in the first rank of medical men, it is incumbent on them to show an honorable example to those who occupy less prominent positions and yet are subject to the same code of ethics. As you have opened this subject, allow me to improve the opportunity to call attention to doings which I consider even more objectionable, committed thoughtlessly, no doubt, by prominent medical men of Philadelphia, for whom I have the highest respect,—men of unimpeached honor, incapable of meanness or trickery in the profession. I am, to speak frankly, glad of this opportunity, because it has been my fortune during the last three years to see two skilful and intelligent physicians in the interior of the State expelled from their society, and subjected to disgrace and pecuniary loss, for violations of the code of medical ethics less grave than those which I shall present.

In the early part of last summer, when your citizens were preparing to go to sea-side resorts, there appeared in the daily papers a letter from a prominent physician of Philadelphia, purporting to be the answer to an inquiry addressed to him by the proprietor of a large boarding-house at Atlantic City, in relation to the merits of that place as a residence for invalids or seekers after health. In this answer the physician alluded to gave at great length a glowing account of the great advantages, in a sanitary point of view, of that locality over all others on the New Jersey coast. I have not now the paper before me, and cannot enter into details. Suffice it to say that the article was extensively copied by other newspapers, with the name of the physician, and name of street and number of residence, and that the letter became the theme of conversation among those who contemplated a visit to the sea-shore, and the very important information which it was believed to contain was hailed by them as a true "God-send." Many turned their steps towards Atlantic City who had before preferred other resorts. I was impressed with the impropriety of the letter on first seeing it; but how was

that impression deepened when I afterwards learned that its author was during *the season* located there as a physician! Could any mode of advertising one's self be more efficient? I do not wish to speak harshly of it; my object is only to present it to the profession as a violation of the spirit, if not of the letter, of the code of medical ethics.

Again, during last summer, the Obstetrical Society of Philadelphia, feeling the importance of disseminating information among the masses in relation to the proper mode of caring for young children during the warm summer months, appointed a committee to draw up "rules" to guide parents and nurses in the management of infants and young children. The committee, composed of six of their number,—men who had had long experience in the treatment of children,—published for distribution ten thousand copies of those, in many respects, admirable rules, and threw them broadcast over the city. But I was grieved to see that their names were appended to the rules. I exonerate every one of them from any intention to gather advantage to himself from the act, but I ask what would be the probable effect of such a proceeding? Would not every anxious mother whose child should show symptoms of indigestion or of cholera infantum say, "One of those gentlemen of the committee would be the proper person to call to my sick child; they are *the* physicians of the Society, specially chosen to issue the address on account of their great experience in the treatment of the diseases of children; and especially those diseases which, from their known fatality, bring sorrow to thousands of homes"? Hundreds who perhaps had never before heard of some of them would thus be impressed with their superiority over all others, and would be inclined to seek their aid in those affections. Would not the rules have been as much respected, would they not have been as authoritative, if signed by "The Committee of the Obstetrical Society," or by its Secretary, as by those gentlemen? I think it was a bad precedent, and has already been productive of evil results. Cannot any physician say, If they can publish "rules," and send them all over the city with their names appended, why cannot I do it? And already we find that a committee is dispensed with, and a single physician issues "directions for the management of infants during the warm weather," signed by his name with title added. And those directions—very objectionable ones too, some of them—are sent broadcast after those of the committee. Surely this is quite as reprehensible as that you charge against the surgical and medical staff of the hospital. If you may publish "directions" or "rules" for treating "summer-complaint" and other diseases of *warm* weather, may not I publish my skill or knowledge in relation to pleurisy, pneumonia, and croup, and other diseases of *cold* weather?—ending with the pleasant and cheering advice, "If you are sick, send at once for a physician"? "And who knows more about the diseases of cold weather than the author of the directions?" would at once suggest itself to the sick man or his family. Were

we to see papers such as I have noticed published by a committee of a homœopathic society, or by an individual of that faith, we should regard it as quite unprofessional, however innocent they might have been of any but the most philanthropic motives. It is most commendable to instruct the community in the art of health; but, in doing it, let it be done for the public good and in the interests of humanity alone.

I hope this article will give no offence to those to whom it refers. My desire is that we of the State shall have a proper example set us by those who so well know the letter and spirit of the code of medical ethics.

HIRAM CORSON.

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

JANUARY 5, 1874.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

MR. HOLMAN'S "siphon slide" for the microscope was exhibited in operation by Dr. Joseph G. Richardson, who remarked that the apparatus was composed essentially of a strip of plate-glass, of the ordinary length and width (namely, three inches long by one inch wide), but double the usual thickness, in the upper surface of which had been ground a shallow groove, elliptical in both its transverse and longitudinal section, and deeper towards one extremity. The excavation was so arranged as to receive a small fish, tadpole, or triton, and retain it without, on the one hand, injury from undue pressure, but without, on the other, permitting any troublesome gymnastics beneath the thin glass cover, which, when applied, formed the ceiling of the cell. The great improvement of this slide consisted, however, in the imbedding of a small metallic tube (communicating with each extremity of the groove) in either end of the slide, and the adaptation to these two tubes of pieces of slender caoutchouc pipe, about eighteen inches in length, one of these being intended for the entrance and the other for the exit of any fluid, *cold* or *hot*, which it might be desirable to employ.

For examination of larger reptiles, and for demonstrations with the gas-microscope, a slide four inches long, with two oval concavities, and a narrow groove more deeply cut for the body of the creature, as shown in the figure, has been devised. With such an apparatus, through which a current of ice-water can be passed, the injurious heating effect which ordinarily attends the use of calcium or electric light to illuminate living specimens is entirely counteracted.

When in use, it is only necessary to place the animal (in the case before us a little triton) with some water in the groove of the slide, cover him with a sheet of thin glass, immerse the end of one of the caoutchouc tubes in a jar of water, and then, applying the mouth to the extremity of the other rubber pipe, make sufficient suction to set up a flow of the liquid through the apparatus. The stream of fluid (of course bathing the animal in the cell during its passage) can readily be kept up, as in any other siphon, for hours or days, and its rapidity exactly regulated by graduated pressure upon the entrance-pipe, so that in this way a triton may be examined continuously (as stated by Dr. J. Gibbons Hunt,

who had kindly furnished and prepared the slide and specimen) for a whole week without material injury.

Among the great advantages of this very ingenious contrivance may be enumerated—first, its security,—the animal being prevented from escaping, and the joints of the apparatus being kept tightly closed by the pressure of the atmosphere; second, its portability,—the whole preparation, for example, one for showing the circulation of the blood, being made at home,—as was done in this instance,—carried to a lecture-room in the pocket, and exhibited to an audience hours afterwards; and third, its convenience,—this arrangement permitting the removal of the slide at any time from the microscope-stage, to make way for other experiments, and its instant readjustment when desired.

Dr. RICHARDSON invited the attention of members to the remarkably clear and distinct view of the circulation displayed by the aid of this apparatus in the caudal extremity of a triton, beneath one of the microscopes upon the table, and pointed out as especially worthy of note the marked prominence of nuclei in epithelial cells covering a portion of the tail, where blood-stasis had occurred, in consequence of a minute puncture purposely made before incarcerating the reptile; suggesting that this change was doubtless the visible exponent of that pathological alteration of the circumjacent cellular elements which constitutes such an important, although as yet but imperfectly understood, factor in the inflammatory process.

GLEANINGS FROM OUR EXCHANGES.

TREATMENT OF LUMBAGO (*The Lancet*, December 27, 1873).—Dr. G. V. Poore reports the case of a man, æt. 35, who had the following history:

He had been accustomed to lathe-work, moving the treadle with his right foot, but had been unable to work for six years on account of a pain at first affecting the backs of the thighs and hips, but afterwards settling in

the lower dorsal and lumbar regions. It was of a plunging, shooting character, much aggravated by the slightest movement, or even by the most gentle touch; he was bent almost double, and walked with the greatest difficulty. The intercostal muscles on both sides were affected, but there was no sign of any disease of the vertebræ or of the cord, and no particularly tender points were detected along the spinal column. He had been subjected to a great variety of treatments, but without any permanent relief having been afforded him.

The positive pole of a zinc-carbon battery was placed at the upper part of the spinal column in the median line, and the whole back, including the intercostal muscles, was sponged with the negative pole. During the application the patient was made to exercise his muscles rhythmically by bending, extending, and rotating the spine, and by frequent inspiration. The effects of this treatment were apparent from the first: the pain was immediately and greatly diminished, if not abolished, and in a short time all the extreme symptoms disappeared.

The important point was apparently the rhythmical exercise of the muscles, which improved their nutrition; but without the anodyne application of the galvanism such exercise would have been impossible.

RESUSCITATION FROM CHLOROFORM-NARCOSIS (*The New Orleans Medical and Surgical Journal*, November, 1873).—In the course of an extended experience in the administration of chloroform, it has happened three times to Dr. M. Schuppert that, to all appearances, the narcotized subject died,—that is, respiration ceased, the heart stopped beating, and muscular contractility became extinct. The method he adopted for resuscitating these patients consisted in reversing the body, either by hanging them up by the feet or laying them over a bed or table so that the greater part of the body with the head hung down. In that position artificial respiration was also tried. In one case five minutes elapsed before there was a natural inhalation. All of them recovered. Dr. Schuppert believes that in cases of death from chloroform the primary cause of the cessation of the respiration and circulation rests in anæmia of the brain, and not in impregnation of the blood with carbonic acid.

ACETIC ACID IN PSORIASIS (*New York Medical Journal*, January, 1874).—Dr. Buck, of Lübeck, says that by ordinary methods of treating psoriasis the eruption may be temporarily removed without difficulty, but no protection from relapses is afforded. He believes that in nearly all chronic cutaneous eruptions, and especially in psoriasis, an etiological treatment is impossible, and a permanent result is promised only by a consistent external treatment. He has obtained the best results from the use of acetic acid. After the epidermal growths have been softened and loosened by several warm baths and soap, the glistening scales are removed with a soft brush. At first a few points of the eruption are to be pencilled once a day, and this is to be repeated until the skin remains smooth and feels normal to the touch. There are never any scars left. The treatment lasts from four to six or eight weeks, and, properly carried out, is not followed by relapses.

PARACENTESIS THORACIS (*The Practitioner*, December, 1873).—Dr. Sydney Ringer publishes his notes on five cases of paracentesis thoracis, showing by them how slight a disturbance this operation causes and what immense relief it affords; showing also that the operation may be usefully employed in the febrile and non-febrile stages of pleurisy with effusion, and that during fever the fluid may be withdrawn by the aspirator and not accumulate again. In some cases of empyema it is suf-

ficient to withdraw part of the fluid by the aspirator,—the rest may disappear; so that it is not always necessary to lay open the chest in order that the pus may drain entirely away. In severe empyema the temperature may be normal, or scarcely at all raised; and in those cases accompanied by chronic fever the pus may be perfectly sweet.

CHOLESTERÆMIA (*The Medical Record*, December 1, 1873).—In a paper read before the New York Academy of Medicine, Prof. Austin Flint, Jr., discussed the condition which has been called cholesteræmia, and concluded that cholesterine is an excrementitious substance, produced chiefly by disassimilation or physiological wear of brain and nervous tissue; that it is taken up by the blood and carried to a special organ for its elimination, and that that organ is the liver. In the liver it is separated from the blood, and finds its way into the bile discharged into the small intestines, and is there changed into stercorine, which is discharged from the body at about the rate of ten grains each twenty-four hours. In certain cases of disease of the liver, accompanied by grave nervous symptoms, there is an accumulation of the cholesterine in the blood, giving rise to cholesteræmia.

MISCELLANY.

THE NEW HOTEL-DIEU.—An order in due form of law has been served upon the contractors for the construction of the new Hôtel-Dieu, to summon them to recommence work, which has been suspended for some time.—(*Various Journals*.)

We would prefer that the ridiculous edifice known as the Hôtel-Dieu should be utilized, whether for a post-office or for the administration of some other branch of public business. It is only necessary to visit the squat and crowded buildings, lacking both light and air, to be convinced that they will never make a good hospital.—*Le Progrès Médical*, December 13, 1873.

NEW FOSSIL MAN.—In the *Revue Scientifique* for December it is stated that a third skeleton of a troglodyte has been discovered by M. Rivière in the caves of Mentone. This new skeleton, judging from the various and numerous implements by which it was surrounded, lived at an epoch far more remote than that assigned to the skeleton now in the Museum of Paris. The instruments of warfare and other objects found with it, though composed of flint and bone, are not polished. They are only sharpened, and by their coarse execution appear to belong to the palæo-lithic age. On the upper part of the skeleton was a large number of small shells, each pierced with a hole, which appeared to have formed a collar or bracelets. No pottery nor any bronze object was found.—*London Lancet*.

REMOVAL OF GLASS STOPPERS.—It may not have occurred to every one—at all events, it is not noticed in any of our treatises on practical pharmacy—that the easiest way to take out a stopper which has become fixed in the neck of a bottle is to reverse the motion given to it when putting it in, that is, to knock the stopper from *right to left*. In most instances, when a stopper is fixed without the intervention of an adhesive substance, it is by turning it as one would drive a screw.

The direction is almost invariably from left to right, and thus a thread is formed, which it is easier to follow backwards than to break.—*Canada Medical Record*.

GLYCEROLE FOR CHAPPING OF THE SKIN.—

R Oxide of zinc, gr. xx;
Tannic acid, gr. xv;
Glycerin, ʒix;
Tincture of benzoin, ʒss;
Camphor, gr. xv.—M.

—*Canada Medical Record*.

It is stated that the total export of coffee from the island of Ceylon in the year 1837 was 30,000 cwts., valued at less than 100,000*l*. In 1870 the export was over 1,000,000 cwts., equivalent to fully three and a half millions of pounds sterling in the consuming markets.—*Food Journal*.

UNIVERSITY OF NEW YORK—MEDICAL DEPARTMENT.—Professor Henry Draper having resigned the Chair of Physiology in the University of the City of New York, Professor J. W. S. Arnold will lecture on that subject during the remainder of this session.

HEADACHE.—Dr. C. C. Vanderbeck recommends the use of ergot in headache; thirty drops of the tincture every half-hour until relief is obtained. He regards it as a very useful remedy, though not a specific.—*Boston Medical and Surgical Journal*.

NOTES AND QUERIES.

UNIONTOWN, PENNA., January 9, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—Biddle's *Materia Medica* (p. 294) gives the symbol for calomel as one equivalent of chlorine and mercury each, and says it is a protochloride of mercury; while Rand's *Chemistry* (p. 277) teaches me that corrosive sublimate is equal parts of chlorine and mercury, and that it is a protochloride.

By telling me, through your columns, which of the above is correct, you will much oblige

A MEDICAL STUDENT.

Answer.

THE difference in your authorities is due to the fact that the equivalent of mercury is sometimes considered as 100 and sometimes as 200. Although there are many arguments in favor of the smaller number, the latter has been more generally employed.

According to the new nomenclature, which makes the combining weight of mercury 200, calomel is the protochloride, and corrosive sublimate the bichloride.—Ed.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held Wednesday, January 28, 1874, at 8 o'clock P.M.

Dr. William Goodell will make remarks on the rapid dilatation of the womb for the treatment of some uterine affections.

All regular practitioners of medicine are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 13, 1874, TO JANUARY 19, 1874, INCLUSIVE.

CAMPBELL, A. B., ASSISTANT-SURGEON.—Assigned to duty at Fort Clark, Texas. S. O. 4, Department of Texas, January 8, 1874.

SATURDAY, JANUARY 31, 1874.

ORIGINAL COMMUNICATIONS.

SPINAL CONGESTION AND LOCOMOTOR ATAXIA.

BY GEORGE M. BEARD, M.D.

(Concluded from page 259.)

IN regard to posterior spinal sclerosis, to which spinal congestion sometimes leads, I have these remarks to offer:

1. The great exciting causes of the disease are exposure to wet and cold, mechanical injury, and syphilis. It is a fact not thoroughly appreciated by the profession or by the people, that it is as possible to take cold in the cord as in the lungs. Those who sit for a long time on the cold, damp ground, or ride all day in an open buggy, or sleep in a draft of air, or suddenly leave off in cold weather the underclothing, or sit for hours with wet or even damp feet, and in chilly rooms, or work all day exposed to showers and biting winds, or lie down to rest in wet garments, render themselves liable to take cold in the spinal cord. Cold in the cord manifests itself just as cold anywhere else manifests itself,—that is, by congestion; and if the colds are repeated, the congestion becomes a fixed condition that is not easily resolved, and in time may go on to the condition known as posterior spinal sclerosis, or locomotor ataxia.

The connection between this structural lesion of the cord and exposure to wet and cold is not always directly apparent, is but rarely suspected by the patient, and almost never inquired into by the physician, partly because of its remoteness, and partly because the professional mind, at least, has been diverted in the direction of sexual excess as the one great cause of ataxia. The connection is remote because a long time, usually months and years, intervenes between the exposure that gave rise to spinal congestion and the sclerosis of the posterior column to which neglected and repeated congestions lead. In the case of the cold on the lungs or bronchial tubes, the bad effects follow speedily, and some of the symptoms are tolerably well recognized even among the laity. A cold in the cord manifests itself by symptoms of which the people know little or nothing, and to which the great body of the profession has given but fragmentary attention. It is oftentimes only by close and careful questionings, repeated at different visits, that we are able to trace the relation between ataxia and congestion resulting from cold.

The mechanical injuries that most frequently give rise to sclerosis of the cord are severe blows and falls, or the shock of accidents of almost any kind. It is not necessary that the injury, whatever it may be, should be received on the spine or head, in order to cause symptoms of ataxia. A violent concussion from any injury that is directly felt on the arms or legs may have the same effect as a direct injury to the back. A mechanical injury may cause

chronic inflammation of the cord that may attack either the posterior column alone, or both the posterior and anterior columns. There is sometimes a loss of both sensation and motion, showing that the cord is involved through its whole diameter; as in the case of taking cold in the cord, the ataxy-symptoms may not follow the injury until after several weeks or months. In a case of ataxy,—a medical man who was under my care, and for whom I testified in court,—there was indubitable evidence that the disease was the direct effect of an injury from falling while attempting to get on a horse-car; but the ataxy-symptoms did not appear at once, and were not even suspected by the patient at the time the suit was commenced, and hence much less damages were claimed than would have been claimed had it been known that he was to suffer from so grave a disease of the cord.

2. The cord is predisposed to take cold by any causes that tend to exhaust it. Among the more prominent of these causes are long marching or violent and wearying muscular exertion of any kind, especially of the sort that draws heavily on the lower part of the cord, excessive intellectual exertion, and sexual excesses. The two latter predisposing causes, excessive intellectual exertion and sexual excesses, operate far less frequently than the purely physical causes. It is muscular more than mental over-exertion that produces that peculiar kind of weakness of the cord that invites congestion and inflammation with degeneration. It is not so much among brain-workers as among muscle-workers, not so much among the delicate, the finely organized and sensitive, as among the coarse, the hardy, and the comparatively tough-fibred classes, that we meet with the most cases of ataxia. It is a disease not of the weak, but of the strong. It is notoriously unfrequent among females,—and females, in modern days at least, are far more delicate than males. The majority of the cases, I am disposed to believe, are those who are, or have been, more or less exposed, whose labors are largely, if not entirely, physical, or who, if they live by brain-work, have been at some time or in some way considerably exposed. If two persons of the same age, both of fair constitution, were subjected to precisely the same mechanical injury, I should expect that the one with the coarser temperament would be more likely to develop the symptoms of sclerosis of the cord. Patients of either sex who are specially nervous or hysterical are not liable to structural lesions of the cord. A kind of antagonism, indeed, seems to exist between the distinctively nervous temperament, the *anæmic* condition of the system, and chronic inflammations of the central nervous system of any form; and when such pathological states do arise in these nervous people, the prognosis seems to be better, and they yield more kindly to treatment, than when they arise in those of a stronger and coarser type.

In regard to the supposed influence of sexual excesses on this disease, the profession must revise its opinion. That sexual excesses constitute an important factor in the causation of nervous diseases must be admitted, but it is not structural so

much as functional diseases that they excite; not inflammation, but exhaustion with anæmia, or perhaps alternations of anæmia and hyperæmia, neurasthænia or nervous exhaustion, cerebrosthænia or exhaustion of the brain, myelasthænia or exhaustion of the spinal cord, hysteria, hypochondriasis, spasms and neuralgias. These are the diseases that sexual abuse invites or aggravates. Organic diseases, with a *coarser* pathology, have usually an entirely different origin. The one maxim in medicine to which my studies lead me is that *functional excess primarily causes functional disease*. Over-use of the brain causes functional disease of that organ; over-use of the stomach causes functional dyspepsia; over-use of the sexual organs causes functional debility of those organs, or of the whole central nervous system. Structural disease may follow all these excesses, but not usually, unless the excess is supplemented by some outside influence. A man may be *worried* into insanity, but not often is he *worked* into it; the stomach may be structurally diseased by bad food, but not, as a rule, by simple overloading with good food; and sexual excess, to excite organic disease, must not only be very excessive, but must be reinforced by other disease-provoking forces.

It is true enough that inquiry into the personal habits of ataxic patients very often elicits the confession that at some period of their lives they have been guilty of what may be regarded as sexual excess; but are they therefore sinners above all other Galileans? How many healthy men in the world are there who have not at some time abused their sexual organs? And yet ataxy is comparatively a rare disease, and those who are its victims do not give any more evidence of excesses than thousands and tens of thousands who will never know what ataxy means.

I have studied this subject closely and carefully with nearly every case that has fallen under my observation, and I am persuaded that, at most, sexual excess can be nothing more than a predisposing cause of ataxy, and that, in this relation even, it does not occupy the first place, if, indeed, it does the second place; and that therefore the minds of our poor patients should in this regard be disabused, that they may not add to the sufferings of their sufficiently terrible disease the agonies of useless remorse.

One plausible reason for suspecting that sexual excess is the cause of ataxy is found in the unnatural sexual desire that so often precedes the ataxic symptoms. The increase of desire naturally calls the attention of the patient to the sexual organs, and almost compels a certain amount of abuse; and when questioned concerning his habits, it is no marvel that he recalls and confesses his recent experience in this respect. Now, this increase of sexual desire is often, if not always, the *effect* of spinal congestion, by which the cord is rendered excessively active; it is a sign, not of health, but of disease. It is not, however, nor is the abuse which it invites, the cause of the degeneration of the cord into which congestion leads.

The most, then, that can be said of sexual abuse

in its relation to ataxy, is that, by weakening the cord, it may in certain temperaments prepare the way for colds, mechanical injuries, or, perhaps, for syphilis to enter in and take possession.

Prognosis.—The prognosis of this disease under electrical treatment alone, or in combination with drugs, may be thus generally stated. A very small proportion of cases apparently recover; a considerable number are very greatly benefited in all the leading symptoms; about the same number are but slightly benefited; and in a few cases absolutely nothing is accomplished.

The proportion of absolute cures is so small that there is a natural temptation to doubt the diagnosis or pathology of any reported cure. The cases that are brought on by mechanical injury, especially by concussion, offer the best prognosis; and this is true, I believe, of other nervous disorders. The explanation would appear to be that the disease excited by concussion is of a temporary, and comparatively transient, character, and the character of the lesion is far less severe than in those cases that come on slowly, through long years of incubation. In my observation, the most satisfactory improvement has been in those cases of ataxy that were brought on by concussion. This is also true of paralysis in general, excepting, of course, those cases where the spinal cord is directly and seriously injured.

Most of the published statements in regard to the prognosis of the disease under electricity, as indeed under any other form of treatment, must be received with great caution. Many of the physicians who report the cases have perhaps never before seen a case where they made the diagnosis of ataxy, and in the instance that they publish there is much probability of deception; and this probability is increased if the patient perfectly and permanently recovers. Hysteria comes in to complicate the diagnosis, and some of the reported cures have been, without doubt, of an hysterical character. Spinal congestion is very often mistaken for spinal sclerosis; the symptoms run into each other, and the former in some cases leads to the latter. But spinal congestion is relievable and curable, while spinal sclerosis is rarely so. Some of the supposed cures have been very likely simply remissions in the course of the disease.

I make these remarks not by way of discouragement, but rather to correct two opposite and prevailing errors: first, that ataxy is incurable; secondly, that it is frequently cured. It is midway between these extremes that the truth lies. The prognosis under treatment by electricity is favorable enough to give us encouragement to try our best, and to persevere. Sclerosis is to the spinal cord what tuberculosis is to the lungs; *tuberc dorsalis* (such was the old name of ataxy) and *tuberc pulmonalis* are in prognosis alike bad and dreary. Both diseases mean business, and come to stay. Neither yields without a struggle,—a long one and a hard one. Both are treacherous, and may suddenly reappear when we suppose them to have fled forever. But the prospect in consumption, bad as it is, is yet sufficiently good to stimulate us to the hardest efforts to fight the enemy. It is very different from cholera,

when we give our powders every hour until the patient dies. Now and then a consumptive patient gets well, and remains well; there are many who, by hygiene and treatment, will lengthen their lives by months or years, and wonderfully mitigate suffering. There are others over whom the disease marches like an overwhelming flood, bearing everything before it. Now, to all this spinal sclerosis is parallel, with this difference, that its progress is very much *slower* than that of tuberculosis. Consumption is a disease of months; ataxy is a disease of years. So far as I know, only one of the cases that I have seen has died; and in his case the disease was complicated, and he was guilty of great imprudence. I have known of a number of cases where the patients have lived ten, fifteen, and twenty years, and are living, and in some cases useful and tolerably happy, to-day.

It has been the fashion among some to decry all attempts to treat locomotor ataxy, because, as they say, the pathology is against us. They who say this forget three things: *first*, that it is possible by treatment to *arrest* disease when you cannot cure it. What should we say of a farmer who would make no efforts to stay a conflagration that had already destroyed half his forest, and, unless stopped, would soon destroy all the rest, and perhaps his house with it? To arrest a disease in certain stages sometimes amounts to a substantial cure. Every organ of the body is given in excess of actual needs of existence: we have more liver, more stomach, more lungs, very much more sexual power, and even more of brain and of spinal cord, than are required for simple existence or even for tolerable health and happiness. Experience has demonstrated over and over again, is indeed constantly demonstrating on every hand, that the liver and stomach may be so seriously diseased as to lose a considerable fraction of their functional capacity, that the sexual power may be half destroyed, that a large fraction of a lung may be obliterated, that even a portion of the brain may be scooped out, and yet the man thus maimed remain measurably strong and active and happy and attain a good old age. If, now, one can get along with half or three-quarters of stomach, or liver, or lung, or sexual power, or with nine-tenths of a brain, why may we not get along with perhaps three-quarters or four-fifths of a spinal cord? And if the treatment of ataxy is begun in time, while yet only one-quarter or one-third of the cord is degenerated, why may not the disease be arrested at that point, and the rest of the cord saved? In tuberculosis, as every dissecting-room reveals, there may be positive arrest of the morbid process at various stages; the ruined portion of the lung is not restored, but the healthy portion is saved further ravages, and the scar and cavity remain, and the patient dies years and years afterwards of some other disease. Now, if it were as easy and as common to examine the cord as it is to examine the lungs, I suspect that not a few cases would be found where sclerosis had begun but had stopped,—the diseased portion remaining diseased, and the healthy portion doing the duty of the whole cord, and allowing the patient to die of some other disorder.

Secondly, the skeptics forget that the portion of the cord not diseased may be stimulated and toned and strengthened by treatment so that it does its duty better. Different parts of an organ may act vicariously, so that when one is injured the other may in a measure take its place. Something in the nerve-force imperfectly analogous to collateral circulation takes place, we may believe, in any localized disease of the cerebral nervous system; for organs and parts of an organ but rarely do their uttermost in every direction, as enormous force is kept in reserve only to be called out in great crises. Disease of any part of an organ calls out this reserve force; and the application of electricity—one of the most potent of all means for improving nutrition—and the use of tonics and nerve-food may enable the overworked organ to perform its extra duty without exhaustion.

Thirdly, these critics forget that bad and painful symptoms may be relieved, even when the disease is not arrested. The anæsthesia and the hyperæsthesia, the numbness and the horrible neuralgic pains of ataxia, may be relieved greatly by electrical treatment rightly directed, even when the lack of co-ordinating power is not a whit improved. Again, coming back to my illustration, what intelligent physician is there who coldly folds his arms in the presence of consumption in the first or even second stage? Do we not all of us rather send our patients South and West, and beyond the sea? Do we not ply them with cod-liver oil and phosphates, with good food and gay society, in the hope and expectation that there is possibly one chance in ten of a cure, and one chance in ten of grateful relief and prolongation of life? With a similar hope may we treat our ataxic patients with electricity, ergot, phosphorus, and nitrate of silver,—and to all these we may add hygiene, especially in the form of *rest*; which, as Dr. Mitchell has well pointed out, is of much efficacy in this disease. It used to be said that if a man got well of consumption he never had consumption. We now know better. The question has ceased to be a question at all. A few years since, a friend of mine—one of our most eminent and laborious editors—consulted me for symptoms so serious that I took him for consultation to Dr. Austin Flint, who made a clear diagnosis of tuberculous deposit in one lung. Under time, hygiene, and cod-liver oil and whisky, he not only improved, but, as Dr. Flint has stated, recovered, and is well to-day, and is one of the most laborious men in the land. When I was a member of Yale College, ex-President Day of that institution died at a very advanced age; and on post-mortem there was found in one lung a cavity that had healed thirty or forty years before, when he was a young man, and was expected to die of consumption.

Years hence, when our means for examining the morbid spinal cord are more complete and diffused, it is possible that we may cease to be surprised or skeptical when we hear of the cure of posterior spinal sclerosis.

Treatment.—Ataxia may be treated electrically by a combination of several different modes of

application: galvanization of the spine, central galvanization, and general faradization, when cerebral disturbance or general ataxy of the nervous system appears; galvanization of the cerebral sympathetic, and peripheral faradization with sponges and the metallic brush. All these various applications may be made with weak or strong or medium currents, according to the wants of each case.

The principles on which the electro-therapeutist treats ataxy are typical of the principles on which he will be likely to treat all forms of disease; they will of themselves suffice to indicate to what school he belongs. He who holds the half-truth that only the seat of disease should be treated will confine himself to electrization of the spine; he who cherishes the delusion that the faradaic current cannot affect the nerve-centres will use in this disease only the galvanic current; he who blindly adopts the wild generalizations about the differential action of the ascending and descending currents will prefer either one or the other direction, according to his pathological theories; he who interprets all local disease to be the result and expression of general disease will at once resort to general and central applications; he who suspects the sympathetic to be the subtle source of all human woe will furiously galvanize the cervical ganglia; he who knows nothing about pathology or theories, and cares nothing about them, will empirically treat the symptoms. The wise and well-cultured physician, with eyes open both to pathology and to experience, will try all methods, and in the light of the results will hold fast to those which in each case seem to do good. I have found good results from simply treating the leading symptom,—the anæsthesia,—without any special reference to the cord. I do this by means of the metallic brush, or by a finely-pointed metallic electrode, making the application over the feet, legs, arms, and all parts of the body that are anæsthetic. The end justifies the means. I have found more good, in some cases, from this method, than from galvanization of the spine and all the other methods combined. When the anæsthesia is profound and permanent, currents of great strength are sometimes not only not disagreeable, but positively agreeable.

In recommending this method I do not recommend exclusive reliance upon it: it is to be used in alternation with the other methods of which I have spoken. It should not be forgotten that the reflex effect of powerful peripheral faradization on the cord may be of greater service than galvanization of the spine.

I illustrate these statements by two or three cases.

Posterior spinal sclerosis; concussion of the spine complicated with attacks of aphasia and aching. Very unusual improvement under galvanization of the spine and nitrate of silver.

Dr. N., a medical gentleman, over 70 years of age, was brought to me November 9, 1872, by Dr. Corey. About six months before, the doctor undertook to get on a street-car, but, the iron support being loose, he slipped, and fell on his hip and leg, and for this he was treated surgically. He was laid up with the injury to the leg and hip for some weeks. Certain nervous symptoms also began to appear after a few weeks, but

they were not referred to any injury of the cord, and spinal sclerosis was, very naturally, not suspected. Dr. Corey had made the diagnosis of degeneration of the cord before bringing him to me, and this diagnosis corresponded with my own. The patient had a stiff and uncertain gait, and could not turn round quickly without falling, nor stand still when his eyes were closed. A strange complication was occasional attacks of utter inability to speak, accompanied with suffusion of the face and shedding of tears. These came on under any special excitement, and lasted from one to five minutes.

The anæsthesia and *analgesia* of the lower limbs were profound, and electro-sensibility was but slight; but there was no loss of electro-muscular contractility, and no motor disturbance whatever. There was also a deficiency of the sense of pressure, as indicated by the *piesmeter*. At night there was great pain in the back, with a sensation of numbness that often compelled him to rise and walk the room.

As the patient was entirely well at the time of the accident, and as the symptoms of sclerosis followed or at least began to appear a few weeks after the accident, and as there was no evidence of exposure of any kind, it was clearly a case of *traumatic ataxy*.

The case was subsequently brought into court, in order to collect damages of the railroad company, and was decided in favor of the patient. Being called upon to testify, I gave it as my opinion that the disease from which the old gentleman suffered was of so grave a character that he would never recover, but would be a great sufferer until he died.

I subsequently treated him by mild galvanization of the spine, and nitrate of silver, and in the course of a month he began to improve, and, what is more remarkable, the improvement continued. He did not fully recover, but came nearer to a permanent recovery than any other case that I have yet seen. He was able to resume the practice of his profession.

Posterior spinal sclerosis beginning in spinal congestion. Some improvement under faradization with the metallic brush.

Mr. D., a gentleman 50 years of age, was referred to me March 17, 1873, by Dr. T. M. Markoe. The patient was of a strong build, and of a sanguine lymphatic temperament; during his whole life prior to this disease he had known nothing but health. One year before, he had attended a sale of pews in a church, and for three hours had sat quite still in a cold room. He went there in absolute health; he came out with a feeling of numbness in the legs, which extended to the hands. He was never well again.

On examining him, I found persistent and profound anæsthesia of the hands and feet, and even of the arms and legs. Tingling and pricking and stinging sensations were felt. Sexual power was diminished, but not destroyed. He could stand with *closed eyes*, but could not turn quickly round. Tests with the dynamometer showed good, strong muscular power. At times he had suffered from sharp, shooting, neuralgic pains in the legs. The diminution in electro-sensibility was so great that very powerful faradaic currents applied with the sponge caused *little or no pain*, although the *prick of a pin was quickly felt*. The patient walked quite comfortably, and attended to his business. The treatment used at first was galvanization of the spine, combined with ergot and nitrate of silver internally; but all did no good. I then tried general faradization, and last of all faradization with the metallic brush. The latter accomplished something,—reduced the anæsthesia and relieved a little the abnormal subjective sensation.

Posterior spinal sclerosis; numbness in all the extremities; no impairment of motor power; very little neuralgic pain; remarkable feeling of coldness apparently by taking cold after exertion. Some improvement under central galvanization and nitrate of silver.

Mr. T., aged 51, married, a stone-cutter, was brought by Dr. Tuthill, February 2, 1872. Two years before, while working very hard at his trade on snowy and damp ground, he was taken with numbness and feeling of heat in his legs. All his life he had been of rather nervous organization, and was easily moved to tears. At that time there was no affection of the bladder; the sexual power was unimpaired; very little neuralgic pain, and had been little; there was no pain in the back, but the bowels were costive, and there was a feeling as of a cord around the abdomen; a feeling of heat and burning in the bottoms of the feet was noticed. His legs were *remarkably cold*; oftentimes they felt as though they *were naked*. His eyes were readily suffused with tears. After a month of treatment by central galvanization and nitrate of silver, he left, improved somewhat, but not markedly, in all the symptoms.

There are three general facts of interest in locomotor ataxia that are worthy of note.

First, it is more frequent, so far as I can learn, in the North than in the South; cold, damp climates favor its development. In the early stages, long residence in tropical or subtropical regions is worthy of trial.

Secondly, it is very often complicated with congestion and sclerosis of the anterior column. The neuralgic pains, of which so much is said, do not appear in much more than half the cases. I am not yet able to say whether they are a good or a bad symptom. One thing is sure, the worst and most obstinate cases I have yet seen had no neuralgic pains. Another point equally true is, all the characteristic neuralgic pains may exist in those who never have ataxia.

Thirdly, the results of treatment here, as in all nervous diseases, must depend on the mental organization of the patient: a strong, resolute patient will live when a feeble, timid patient may lay down his armor, give up, and die.

PRURITUS HIEMALIS.

BY JULIO J. LAMADRID, M.D.

I FIND in my note-book the following accounts of two cases of pruritus hiemalis, which so confirm the able paper recently published by Dr. Duhring in the *Philadelphia Medical Times* that I think they are of some interest:

Case I.—M. R., a young married woman, aged 20, consulted me on the 18th of October, 1872, about an itching, burning sensation upon the back, especially between and on the shoulder-blades; coming on in the evening, but more severe soon after taking off her clothes, and lasting a few hours after retiring for the night, sometimes preventing sleep, and causing a great desire for scratching, which, if gratified, as was generally the case, left the patient as bad as ever, if not worse, and seldom afforded any relief, as stated by Dr. Duhring.

Upon examination of the parts, I could not see or detect any indications of disease or eruption, except a

few marks caused by the scratching, and a peculiar look of the skin, like goose-flesh, which is often the result of cold weather. There was no indication of uncleanness or neglect of her person. On further examination of the case, I was unable to find any real cause for this trouble; but, on inquiry as to the habits of the patient, I found that the bowels were inclined to be inactive,—in fact, had not been moved for three days. Here I at once saw the indications for treatment, which consisted in the use of laxatives and such means as were in my power to produce a regular action of the bowels. In conjunction with this, I advised the sponging of the affected parts with hot water every night just before going to bed, and found it to give some relief, but often to fail to do any good. In this case I did not use the alkaline bath, as the disease began to get better as soon as the patient's bowels were once more in accordance with the laws of nature.

Case II.—William R., a merchant, aged 25, and husband of the above case, came to consult me on the 30th of October, 1872, with the same complaint as his wife. He had all the same symptoms, with the exception that the affection in this case was confined altogether to the lower extremities, especially on the legs. On examination of the parts, I could not, as in the case of his wife, find any rash or change in the texture of the skin, or see any signs of uncleanness.

On further inquiry, I learned that the patient was suffering with torpidity of the bowels and hemorrhoids. I put him under the same treatment as the above case, but in this instance I prescribed the alkaline bath, with better success than with the hot water. I also attended to his piles by means of iodoform suppositories and such ointments as are usually recommended in the text-books. I need only add that my patient got well soon after the cause was removed,—which I am satisfied was the constipation.

Before I leave this subject, I shall ask the attention of my readers to the fact that the disease in the first case was confined to the trunk or back, a thing rarely to be observed, as remarked by Dr. Duhring. Farther on he says that the disease is unaccompanied by constipation. But, according to my own observations, it is quite the opposite, and I believe this to be the real cause of the disease.

Both parties were again visited by the same trouble during last fall, and again I traced it to the same complaint,—constipation.

BROOKLYN, LONG ISLAND, January 13, 1874.

A CASE IN WHICH BOTH LEGS WERE AMPUTATED IN UTERO.

BY GERALD O'FARRELL, M.D.

NOVEMBER 20, 1873, I was called to see Mrs. A., aged 33, primipara, a native of Ireland. She stated to me that she supposed she was in the sixth month of her first pregnancy, and that she had had frequent hemorrhages during the past six weeks. On making an examination, I ascertained that she was pregnant, but so feeble was the murmur of the foetal heart that I deemed it prudent to express no opinion as to whether it was living or not, although the woman was very anxious to know.

I ordered liq. ferri persulphatis in five-drop doses every three hours, with rest in the recumbent position for two weeks.

December 24 I was called to see her again, and found that there had been no return of the hemorrhage,

but that she was in labor; the os uteri fully dilated, the membranes ruptured, and the breech presenting. The labor was completed about an hour after my arrival.

I observed as soon as the child was born that both legs had been amputated by the funis, the right being entirely removed from below the insertion of the tendon of the patella, the left just above the ankle, with the foot still attached by a small shred of skin. The stumps were cicatrizing, the centres being bright red, with patches of gray lymph on the edges. The two middle fingers of the left hand were webbed. The scalp was thickly covered with gray hair, with the exception of the anterior and posterior fontanelles, which were covered with a greenish fur, such as is seen on the cadaver in the dissecting-room. The funis was black, and became detached from the placenta on the slightest traction. The placenta was entirely adherent, but so soft as to be with difficulty removed entire. The child was a male, and lived twenty-seven hours. The trunk was much more developed than the lower extremities.

Asking the lady if she had met with any shock or accident, she informed me that just prior to the first hemorrhage she had gone to visit a friend, and had worn a very tight-fitting dress. On reaching her friend's residence she became faint, and had to be carried into the open air. From that time she failed rapidly in health. The tissues of the woman were perfectly blanched, and she had a very copious and offensive discharge during the next ten days, when erysipelatous inflammation set in. She was ordered tinct. ferri chlor., gtt. xx three times a day; quiniæ sulphatis, gr. ii every three hours, with a local application of chlorate of potassa in flaxseed mucilage. She recovered perfectly, under the above treatment, in two weeks.

SUPERNUMERARY FINGERS AND TOES.

BY CHARLES W. BROWN, M.D.

DANIEL H. had five fingers and six toes. M., brother of Daniel, feet and hands normal; his only daughter had five fingers and six toes; and her two children's hands and feet were in the same way.

David, another brother, had additional fingers and toes, and his only daughter had only additional fingers.

H., son of Daniel, had six toes on each foot; his hands were normal. His three children had five fingers and six toes.

R., another son of Daniel, both feet and hands the same. He has two boys and two girls. One boy had six toes on one foot. One girl had additional fingers and toes.

I was called to remove the extra members from the last-named case, an infant, then six weeks old. On examination, I found that both feet contained six toes each, and they were normal in shape, with perfect joints, and in the additional toes the usual amount of motion. They were situated the same as the normal small toe, instead of being connected with the great toe, as Dr. Gross says they usually are. So I decided not to remove them.

The fingers were situated at the side of the metacarpophalangeal articulation of the little fingers, at right angles with the normal fingers, and had each a distinct joint, which I disarticulated, forming a flap of skin which covered the wounds completely. They healed readily, leaving no deformity.

All the other cases were nearly the same as the last-mentioned case, except the boy with one additional toe that was situated at the base of the great toe.

MANSFIELD, PENNA., January 16, 1874.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. R. J. LEVIS.

Reported by JOHN B. ROBERTS.

INTRA-CAPSULAR FRACTURE OF THE NECK OF THE FEMUR—THE USE OF WEIGHTED SPLINTS IN THE TREATMENT OF FRACTURES.

AN old woman, while walking across the floor, tripped, and, falling, sustained a fracture of the neck of the femur.

It is necessary in injuries in this situation to be able to make, if possible, the differential diagnosis between intra- and extra-capsular fractures, for the prognosis in the two cases is very different. If the patient is over sixty years of age and the injury caused by such a slight accident as tripping upon the carpet, it is probable that the fracture is intra-capsular, because the bone within the capsular ligament is cancellated, and, becoming with advancing years more earthy in composition, is brittle and readily broken by muscular contraction or slight indirect violence.

Extra-capsular fractures, on the other hand, are usually the result of the application of a great degree of violence, as in a case in the hospital, where a man, in attempting to pull a door-bell violently, was precipitated down a flight of steps to the pavement by the wire of the bell breaking, and sustained a fracture of the neck of the femur external to the capsule.

The shortening in intra-capsular fractures rarely exceeds three-quarters of an inch, for the capsular ligament retains the ends of the fragments in proximity; the surgeon, however, by pressing the bone upward can cause a still greater decrease in the length of the limb. A striking symptom is the peculiar attitude assumed by the injured limb, which is everted so that the external surface of the foot lies almost flat upon the bed, with the heel resting in the hollow above the os calcis of the other side.

It is difficult to obtain crepitation in this fracture, because the head of the bone lying loose in the socket is not sufficiently fixed to permit friction upon it, but moves readily with the motion of the shaft. A sensation similar to crepitus, however, is sometimes perceived, and often considered to be such, when really it is the rubbing of the end of the shaft against the ligaments and edge of the acetabulum. A good deal of injury is sometimes occasioned by repeated attempts to obtain crepitation, which only succeed in rupturing any spicules of bone which, perhaps, may be holding to some extent, by partial impaction, the extremities of the fragments in apposition.

A diagnostic point of great value is obtained by placing the hand upon the great trochanter, and observing the arc through which it moves when the limb is rotated on its long axis by an assistant.

In the normal condition, the neck of the bone being intact, the trochanter moves through an arc with a radius corresponding in length to the distance from the tuberosity to the articular surface of the head of the femur, and the arc of rotation is limited by the acetabulum and the ligaments of the joint; but if the neck be fractured, the motion will be in an arc of a very short radius, though it will be through a greater portion of a circle. In fat individuals it may be difficult to differentially diagnose fractures of the neck of the femur, owing to the impossibility of examining the parts thoroughly. If such be the case, place the patient upon his abdomen, and, having etherized him, see how far the injured limb can be lifted in a backward direction up from the bed, for it will soon be arrested against

the brim of the acetabulum if the neck is intact; but if fractured, the limb can be bent backwards to an abnormal extent.

A feature about these fractures which has a tendency to mislead the surgeon is that the patient is sometimes able to walk a considerable distance after the receipt of the injury, which seems incompatible with the existence of fracture of such an important bone as the femur.

The prognosis in intra-capsular fractures is very unfavorable, for union seldom, if ever, occurs, because of the impossibility of obtaining correct apposition of the fragments, the great effusion of synovial fluid bathing the parts and preventing the formation of callus, and the want of a sufficient supply of blood to the head of the bone, which has its circulation almost entirely cut off by the solution of continuity with the shaft. If, then, it were certain that this was a fracture entirely within the capsule, it might almost be left without treatment; but, as it may be partly intra- and partly extra-capsular, it is always proper in these cases to apply extension as in other fractures of the thigh, to afford an opportunity for union and to relieve pain.

Extension is accomplished by fastening a small board, to which a cord and weight have been attached, under the foot by two long strips of adhesive plaster extending up the sides of the limb near to the hip, so that the ligaments of the knee-joint may not be injured by the traction. The entire limb is then covered with a bandage, and the cord, with a weight of about ten pounds at the end, placed over a pulley adjusted to the end of the bed.

Instead of the ordinary sand-bags usually placed along the limb to restrain its movements, Dr. Levis employs what he denominates *weighted splints*, which are long boxes made to hold three or four bricks placed end to end. These fulfil the requirements more effectually than the bags, for the sand in the latter is apt to work under the limb instead of remaining as a firm lateral support; and moreover they, being cylindrical, touch the limb only by a curved surface, while the weighted splints with cotton or oakum padding present a wide surface, against which the member rests, and by which it is held as firmly as if lateral splints were bound to it by a bandage.

HYDROCELE COMPLICATED WITH INGUINAL HERNIA TREATED BY INJECTION OF CARBOLIC ACID—DIFFERENTIAL DIAGNOSIS OF SCROTAL TUMORS.

A man was admitted into the hospital with a large hydrocele of the vaginal tunic, coexistent with scrotal hernia that was easily reducible, and for which he had worn a truss a long time. There are varied tumors occurring in the scrotum, and it is important to be able to make a correct differential diagnosis, for the mode of treatment adapted to one condition may be altogether inapplicable to another.

Hydrocele is distinguished by absence of pain and discoloration, by an elastic feel, and by the swelling first appearing at the bottom of the scrotum and gradually extending upwards. There is usually, moreover, translucency perceived upon holding the tumor between the eye and the light, especially if a tube, as an ordinary stethoscope, be placed upon the scrotum, and the observer looks through it towards the light. This translucency may be absent if the contained fluid is dark and the skin and fasciæ have become thickened by protracted existence of the condition, or if the tunica vaginalis be lined with plastic matter, the result of chronic inflammation.

In scrotal hernia, which is sometimes confounded with hydrocele, the tumor descends from the upper part of the scrotum, may be traced to the external abdominal ring without difficulty, and usually can be reduced by returning the bowel to the cavity of the abdomen by manipulation. The most certain diagnostic features are

the impulse upon coughing, always perceived in hernial protrusions, but absent in hydrocele, and the position of the testicle, which is found in the former case at the bottom, but in the latter almost invariably at the middle and back of the tumor. Occasionally these two affections coexist, as in this patient; but the two sacs, situated one above the other, present upon careful examination their characteristic signs.

The softness of the swelling and the sensation imparted to the fingers, as of a mass of worms in the grasp, serve to diagnose varicocele; which tumor, moreover, disappears entirely upon raising the scrotum so that the blood may flow out of the veins.

In cases of sarcocele and carcinomatous disease of the testicle the swelling is very heavy, irregular in its outline, instead of having the smooth, ovoidal form of hydrocele, and possesses no translucency whatever. Hæmatocele is also distinguished by weight, but is different from sarcocele and carcinoma in having nearly always a history of traumatism. When these points fail to reveal the exact nature of the affection, the diagnosis can be readily established by introducing an exploring-needle on the end of a hypodermic syringe into the tumor.

In this case there was no translucency, but upon puncturing the swelling a dark fluid escaped, which proved it to be a hydrocele, and at the same time showed the reason for its opacity.

The most popular method for the radical cure of hydrocele is the injection of stimulating fluids into the vaginal tunic, after the withdrawal of the serous effusion by the trocar. Of the various injecting fluids proposed, tincture of iodine is most generally employed at the present day; but it often fails to produce the inflammation requisite for the obliteration of the sac, and occasionally induces too much inflammatory action. Dr. Levis prefers carbolic acid for the injecting material, and in this instance used one drachm of a mixture of equal parts of carbolic acid and glycerin.

The injection of carbolic acid seems, from other cases to which it has been applied, to fulfil the conditions most admirably, producing sufficient inflammatory action to secure adhesion of the walls of the sac, and giving little or no pain to the patient, either at the time of its introduction or subsequently. This freedom from pain is probably due to the local anæsthetic effect of the carbolic acid, for it is well known that if this article be placed upon the skin the surface can be scarified with a knife without pain.

There is no danger of the inflammation being transmitted to the hernial protrusion, for experience has shown that this does not occur after injections for the cure of hydrocele complicated by the existence of scrotal hernia. It would, however, be a dangerous procedure in congenital hydrocele, since there the vaginal tunic communicates with the peritoneum, and inflammation of the latter membrane might be induced by continuity of structure.

When, as in this case, the tumor is very large, the fluid should be withdrawn simply once before attempting the radical cure, so that the sac may be contracted and the tumor reduced in size; and then, after the fluid has reaccumulated to some extent, the sac can be again evacuated and the stimulating material injected, so that the inflammation may be restricted to a diminished surface.

ABSCESS OF THE LIVER OPENING INTO THE ASCENDING CAVA.—This extraordinary lesion is reported by Dr. Leon Colin in *L'Union Médicale*, Aug. 5, 1873. Secondary purulent deposits had occurred in the lungs, which, causing a copious expectoration of pus, had during life led to the erroneous diagnosis that the abscess had burst into a bronchus.—*Boston Medical and Surgical Journal*.

TRANSLATIONS.

INFLUENCE OF THE ACTION OF THE SKIN UPON THE SECRETION OF URINE.

DR. MÜLLER (*Archiv für Exper. Pathol.*) has by the aid of appropriate apparatus conducted a series of experiments with a view to determine what influence, if any, is exercised on the quantity of the urinary secretion by variously modifying the action of the skin.

The influence of cold was ascertained by cold packing and by cold showers. The packing was carried out by means of cloths wrung out of ice-water, which were wrapped around the animal to be experimented on, and were renewed every five minutes. The duration of the experiments varied from ten to twenty-five minutes.

Ex. 1.—Rate of secretion 22 drops per minute ;
increased to 27 " "

Ex. 2.—Rate of secretion 30 " "
increased to 41 " "

Ex. 3.—Rate of secretion 24 " "
increased to 31 " "

The use of ice-cold showers gave the following results:

Ex. 4.—Rate of secretion 30 drops per minute ;
increased to 38 " "

Ex. 5.—Rate of secretion 27 " "
increased to 34 " "

Ex. 6.—Rate of secretion 21 " "
increased to 30 " "

The effect of hot applications in the form of cloths wrung out of hot water was as follows:

Ex. 7.—Rate of secretion 26 drops per minute ;
decreased to 7 " "

Ex. 8.—Rate of secretion 34 " "
decreased to 17 " "

Ex. 9.—Rate of secretion 31 " "
decreased to 18 " "

Continuous showers of hot water gave the following results:

Ex. 10.—Rate of secretion 23 drops per minute ;
decreased to 4 " "

Ex. 11.—Rate of secretion 26 " "
decreased to 5 " "

Ex. 12.—Rate of secretion 20 " "
decreased to 4 " "

The influence upon the secretion of urine of frictions of the general surface and of epispastics (blisters and mustard-plasters) was also examined into, but with negative results.

Varnishing the cutaneous surface gave results which were quite unexpected, and in fact seemed almost paradoxical.

In three experiments out of seven a diminution of from two to three drops per minute was observed. No increase in the secretion of urine was observed in any case.

Dr. Müller believes that an explanation for this diminution of the quantity of urine following varnishing of the skin may be found in the statement of Laschke-wisch, that such varnishing is followed by a general dilatation of the cutaneous blood-vessels, which reduces the pressure on the renal circulation.

The importance of these experiments from a pathological point of view may be appreciated by comparing the figures in the series relating to the effect of hot-water wrappings with the well-known good effect of diaphoretics in Bright's disease.

In the latter, a single packing, as is known, often induces a loss of weight amounting to ten pounds.

That this loss represents just so much work taken off the kidneys is evident from a consideration of the figures just mentioned.

It may be easily understood that an organ which is affected in most cases of inflammation can much more easily be cured if the great local hyperæmia can be remedied, or if even a temporary anæmia can be brought about.

It is self-evident, moreover, that an organ whose entire physiological function depends upon its varying blood-circulation could be more easily and quickly relieved from disease if this circulation could for a time be diminished and a temporary rest allowed the organ.

A. VAN HARLINGEN, M.D.

THE ACTION OF SPARTEIN UPON THE ANIMAL ORGANISM.

UNDER the above title, Dr. Fick gives (*Archiv für Exper. Path.*) an account of a number of experiments made upon frogs and other animals with this substance.

His conclusions are as follows: 1. So far as can be ascertained, spartein affects the intellectual functions both of frogs and the mammalia, and can therefore to a certain extent be regarded as a narcotic.

But this effect upon the brain is not a very marked one in degree, since, even in cases where the most decidedly poisonous results have been produced, entire suspension of consciousness has not been observed.

2. Spartein exhibits powerful toxic effects upon the spinal cord, the reflex action of which in particular is lessened to a great degree.

3. Spartein paralyzes the motor nerves, which after a larger dose of the poison lose their electrical excitability entirely.

4. A small dose of spartein causes the suspension of the electrical excitability of the vagus, so that its excitation produces no interfering influence upon the motions of the heart. In larger doses the governing centres themselves are paralyzed, so that neither by the use of muscarin nor by other means can a diastolic cessation of the heart be produced.

5. In the poisoning of mammalia by spartein, death is dependent upon paralysis of the respiratory centres.

By employing artificial respiration, life may be prolonged in the poisoned animals for some time.

A. VAN HARLINGEN, M.D.

VARICOSE AXIS CYLINDERS IN THE CENTRAL NERVOUS SYSTEM.

DR. OTTO OBERMEIR, of Berlin, states (*Virchow's Archiv*, September 10, 1873) that varicose enlargements of the axis cylinders occur more frequently in the brain and spinal marrow than is commonly supposed. A varicose condition of the finest fibres of the cerebellum and in the gray substance of the spinal cord is normal. Enlargements of this character of noticeable dimensions are found in the brain and spinal cord in the course of various acute and chronic inflammatory diseases. Marked thickening and swelling of the axis cylinders were found in two cases of glioma of the cerebral hemispheres, in a case of cystic sarcoma of the cerebellum, in a hemorrhagic spot in the right peduncle of the cerebrum, etc.

Deposits of hæmatin were found in the walls of the adjacent vessels, and free hæmatin in their neighborhood. The existence of the various axis cylinders in these cases in connection with hemorrhagic exudation appears to be due to an inflammatory process from reaction.

WM. ASHBRIDGE, M.D.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 31, 1874.

EDITORIAL.

THE PHILADELPHIA HOSPITAL.

MOST of our readers will remember that last summer we devoted the editorial columns of several issues of the journal to exposing that leprous excrescence known as the Philadelphia Hospital, and protested against the system which labels, clothes, and feeds a man disabled by sickness or injury, as a pauper, and turns him *volens nolens* into a pauper upon his recovery. We intimated that more was to be said upon the same subject if the breach made by our attack was not wide enough for the stream of reform to find its way through, gradually open free passage, and acquire a force which should cleanse the Augean stable. We have since forborne to write upon the subject, for two reasons: First, because so many topics of more general interest have presented themselves; secondly, because we could see evidences that the good work was going on, and might be hindered rather than aided by words of ours.

After the appearance of our editorial, at first astonishment and surprise were expressed in private circles,—words of indignation, making to tingle the ears of those in authority. Then timidly, with bated breath, the newspapers of our city began to say a word or two. Philadelphia's pride, its daily press, leaving the story of the criminal courts or of the last murder, found room for some cautious words in regard to the almshouse, stating that the matter needed looking into, and then, forsooth, swelling with the pride of conscious virtue because it had shown so much of energy and of boldness!

At this juncture there occurred in the office of one of our leading dailies an incident that portrays so vividly the obstacles which reforms like the present meet with, that we insert it:

Young and ardent editor Jones, holding the *Philadelphia Medical Times* in his hands.—“Mr. Smith, look at this! Let us send a reporter and work it up; it will make a first-class thing for us, and do good.”

Old and wary principal Smith.—“Ah! It can't be true. I have some very good friends on the Board; they would not suffer such a state of affairs! It can't be true.”

So nothing is said. The good friends remain good friends, and the city advertising goes on as usual.

Notwithstanding the obstacles, more and more did public opinion crystallize around our protests, until after a time a grand jury condemned very pointedly the Philadelphia Hospital, and we could see some light breaking through the skies. Finally, not long since, the Board of Guardians, through their hospital committee, agreed to or instituted measures which seem to us the entering-wedge for the desired separation of the almshouse and the city hospital. It was agreed that hereafter all patients shall enter the hospital, and not, as heretofore, the almshouse, to be assigned to the hospital department; that a better grade of flour shall be bought for the hospital; that the patients shall no longer be clothed in the dress of the pauper, and that they shall be discharged, at the will of the hospital committee, directly from the hospital, and not simply from the hospital department to the out-wards of the almshouse.

In regard to the condition of the equipments of this hospital, half a century old, it is very significant that it was found necessary to appropriate twenty-five hundred dollars for surgical instruments.

In the name of the poor wretches whom hard fate has driven to the Philadelphia Hospital, we thank the Board which has granted this great boon; in the name of an outraged humanity, we beg of them to go on until the stricken wayfarer shall find that rest and care which it is the mission of Christianity to furnish; in the name of a disgraced community, we demand the most sweeping reforms, until at last this city of a million of people shall have a municipal hospital worthy of the name.

ARMY MEDICAL LIBRARY.

WE learn with great regret that it is proposed to cut down the usual appropriation by Congress to the Army Medical Library from fifty to ten thousand dollars. It is to-day simply impossible to

write in America an exhaustive book upon any large medical subject, because the material out of which such works are built is not at hand. There is no complete medical library in the country, and we see no prospect of there being one except through the attempt at Washington. The crippling of this movement is simply a national misfortune, destroying or putting back many years the growth of the highest medical culture in this country; reaching directly, perhaps, only a few leading thinkers in the profession, but affecting through them the whole body of physicians, and, through the general practitioners, the highest and meanest citizens. We trust that our medical societies will bestir themselves and influence the representatives of their various districts. Would it be possible to awaken that venerable old lion, the Philadelphia College of Physicians? To be sure, he is seemingly harmless,—his teeth wasted away, and his claws worn off,—but perhaps he has enough life left for a lethargic growl, and his former reputation is not yet quite forgotten.

CORRESPONDENCE.

THE FUNCTION OF THE LYMPHATICS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

YOUR notice of Assistant-Professor Klein's "Anatomy of the Lymphatic System" is well timed,* and will do something towards directing attention to this anatomical mystery, hitherto, of the human body. That the function of this elaborate and complicated system of living bodies should have wholly escaped the scrutiny of physiologists need not be an occasion for surprise, since the functions of so many of the organs of the body are so imperfectly understood. In the very latest exposé of physiology (Flint) its function is disposed of in a dozen lines. And the suggestion of Professor Klein that it "may be regarded as ministering to the production and development of blood" leaves the matter as much in the dark as ever. Still, it has a function, and an all-important one, too. Three years since, I think, it fell to my lot to designate its actual function in organic life. In a paper in the *Buffalo Medical and Surgical Journal*, July, 1871, I first gave my conclusions to the profession. Incidentally, since then, I have stated it in several other published papers,—*Medical Press and Circular*, London, March 26, 1873,—though it is more elaborately worked out in the *Chicago Medical Journal*, December, 1873, in connection with an abstract of the debate, a year since, in London, on the "Anatomical Relations of Tubercle to Phthisis."

Briefly, I may say, then, that the lymph performs the

same function in animal life as the seed in the vegetable world. Technically stated, the lymph stores up the force to carry its own and new material up to the special molecular arrangement or forms of organic structure from which it has been derived. It is, in fact, the precise material in which is stored up the so-called "vital force," which plays so important a part in organic life, according to accepted physiological beliefs, in the professional and naturalist minds of the past and present.

The elaborate work of Professor Klein on the "Anatomy of the Lymphatic System" can hardly fail to do something towards clearing up the obscurity in which the functions of the contents of the abdominal cavity are at present shrouded, and may lead to an entire reconstruction of the physiology of "digestion," so called, transferring its seat from the abdomen to the lungs. The changes effected in the few "proximate principles" of which all our food consists—viz., starch, fats, oils, gum, sugar, gelatin, albumen, and fibrin, animal and vegetable, etc., etc.—are not well understood as a whole, though fairly made out in part, as the dissolving of heat-coagulated albumen and fibrin by pepsin, and the conversion of starch into sugar in the liver, etc., etc. But, whatever they are, no part of new material introduced into the stomach probably finds its way to the lungs through the thoracic ducts, but all is taken up by the venous blood-vessels. The stream arriving at the right heart really consists of old and new material, to which the lymph—the seed of the tissues, so to speak—is added just before entering the right auricle. In the lungs this complex stream meets the gaseous atmosphere, where, it seems to me, the facts of observation and experiment demonstrate that the bulk of the molecular or chemical changes occurs to fit food to become living flesh, capable of performing a function, chief among which is provision, in turn, for its own reproduction from new material.

The material in which each and every living histological structure stores up the force, in the act of functional decay, for its own reproduction from new material, it is the special function, it seems to me, of the lymphatic system to take from among the other products of decay, and restore it again at a proper time and place to perform its function. That proper place is just where the thoracic ducts empty their contents into the bloodstream; and in the economy of nature no other place would be proper in the whole body but near the right auricle.

Possibly it would "pay" your publishers to reproduce Professor Klein's beautiful work, and place it within reach of the profession at large in this country; though it is a suggestive fact that it required "government" aid to bring it out in London.

More likely, as it is not a "practical" work,—that is, does not tell how to give certain drugs and medicines to cure certain so-called diseases,—those who want it will have to do as I have done—buy the English edition.

Z. COLLINS McELROY.

* *Philadelphia Medical Times*, Jan. 10, 1874.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, DECEMBER 11, 1873.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

DR. MORRIS LONGSTRETH presented the *brains* and *spinal cords* from the following cases of *cerebro-spinal meningitis*.

Case I.—Martha R., æt. 36, was admitted to the Pennsylvania Hospital April 1, 1873, under the care of Prof. J. M. Da Costa, having been ill for four days. She was delirious, but not noisy; intelligence confused, answering questions incorrectly.

Died on April 5, 1873.

Autopsy was made fourteen hours after death. No marked morbid lesions were found in any of the thoracic or the abdominal organs. The posterior portion of both hemispheres along the longitudinal fissure was covered with a layer of lymph. On the base of the brain the lymph was more abundant, and covered the crura, pons, and the trunks of the cranial nerves. The spinal cord was covered with a thick layer of lymph, measuring nearly an eighth of an inch in thickness, extending throughout its length. The lymph was in the sub-arachnoid space, and was adherent to that membrane; it was quite firm in consistence, and of a grayish color.

The spinal cord only was exhibited, and is preserved in Prof. Da Costa's collection at the Jefferson Medical College.

Case II.—Philip G., æt. 38, was admitted to the Pennsylvania Hospital March 15, 1873, under Dr. James H. Hutchinson.

The surface of the brain has a bright-red appearance, from the intense congestion of the vessels of the pia mater. The lymph exists mostly in the sulci between the convolutions, but in places covers the convolutions also. The congestion is greater on the convexity of the brain, and the lymph more abundant on the base.

The spinal cord is greatly congested, the membranes opaque, and lymph exists in patches throughout its length. There are three or four *calcareous particles* deposited in the lymph.

The notes of the case are published in the *Philadelphia Medical Times* for June 28, 1873, by Dr. Hutchinson, and both specimens are preserved in the Museum of the Pennsylvania Hospital.

Case III.—John L., æt. 33, was admitted to the Pennsylvania Hospital April 15, 1873, under the care of Dr. James H. Hutchinson.

The vessels of the cord are considerably injected; the arachnoid is nearly opaque. The deposit of lymph is most marked at the lower portion; a small portion of the upper dorsal region, however, is completely covered. A few very minute calcareous particles are present.

This case is published in the *Philadelphia Medical Times* for June 28, 1873, by Dr. J. H. Hutchinson, and the spinal cord is preserved in the Museum of the Pennsylvania Hospital.

Case IV.—George Barley, æt. 22, was admitted to the Pennsylvania Hospital May 9, 1873. Notes of the case are in the Register, No. 229, for 1873-4.

The brain is much congested; on the convexity there is some lymph, on the base the surface is quite shaggy with shreds of inflammatory adhesions, and a layer of lymph exists in the sub-arachnoid space. The cord is not markedly congested; the membranes are thickened and opaque. An uneven layer of lymph covers the cords, and in it are imbedded some particles of calcareous matter.

Case V.—Edward A., æt. 35, admitted to the Pennsylvania Hospital April 16, 1873, under Dr. Hutchinson's care. The spinal arachnoid is hazy and somewhat opaque. There are streaks and patches of lymph beneath it, and one or two calcareous points. The vessels of the pia mater are considerably injected, and the consistence of the cord itself is rather soft.

The notes of this case are published in the *Philadelphia Medical Times* for June 28, 1873, by Dr. Hutchinson, and the specimen is preserved in the Hospital Museum.

Dr. J. H. HUTCHINSON said he had had several of these cases reported by Dr. LONGSTRETH under his own observation, but could add nothing to what had been said, except as to the appearance of the spiculæ of inorganic matters beneath the membranes. These were first thought to be spiculæ of bone which had obtained accidental admission in the operation for opening the spinal canal; but examination proved this view to be erroneous, as they were not bone-tissue, but simply inorganic matter.

As to treatment, none seemed to afford relief, except in one instance, where cups to the back of the neck appeared to give great relief. Bromide of potassium also afforded some relief in quieting the patient.

Out of the six cases treated in the Pennsylvania Hospital, five died; and at the post-mortem examinations the lesions discovered were by no means commensurate with the degree of the symptoms,—cases in which the symptoms were most severe and of longest duration showing a simple hyperæmia of the spinal cord, while another, in which there was the history of but two or three days' illness, exhibited extensive changes.

Dr. S. W. MITCHELL said that he had seen a large number of these cases, but his experience had been confined to private rather than hospital practice. As to treatment, his results had been similar to those of Dr. Hutchinson, nine cases out of eleven having perished. Within the last three months he had also met nine cases in which recovery had been attended by absolute deafness, in which also all treatment for the latter affection proved unavailing. He alluded to the recent paper by Dr. Knapp, of New York, in which a large number of cases of deafness following cerebro-spinal meningitis had been collected, out of which two only had been relieved by treatment.

Dr. Mitchell had also met one case of blindness after this affection, in which there was well-marked atrophy of the optic nerve, which had also failed to respond to treatment.

Dr. CHARLES H. BURNETT asked whether in these cases of deafness there was any staggering gait.

Dr. MITCHELL replied that he had met the staggering gait in one case only, but this was very marked, and associated with sick stomach. The latter symptom might have been either a cause or a consequence, but he thought the latter more likely.

Dr. BURNETT had asked the question because he was curious to know whether the deafness and staggering or sailor-like gait were associated. He had recently been informed by a gentleman practising in Pottsville that he had observed deafness following cerebro-spinal meningitis in some twenty cases, in all of which he had observed the staggering gait. Dr. Burnett had himself met one case of the deafness in which the staggering gait was also present.

Dr. LONGSTRETH asked whether the cause of the deafness was centric, or due to some cause acting upon the nerve-trunks, as, for instance, the pressure of the inflammatory lymph.

Dr. R. M. BERTOLET said the cause assigned by Dr. Knapp in the paper referred to was an effusion of pus and lymph in the labyrinth, similar to the effusion in the retina, which causes total blindness. Dr. Berto-

let had seen about twelve cases of deafness following cerebro-spinal meningitis, but the staggering gait was not present markedly in any, and often wanting.

Dr. BURNETT said that cases had been reported by Knapp in which pus had been found in the labyrinth. He thought the best explanation of the deafness had been given by the anatomist Hasse, in a recently published instalment (No. XIX.) of his "Studies of Anatomy," in which he states that, having studied the anatomical relations of the perilymph and endolymph, he had concluded that they are perfect and complete portions of the lymphatic system, and that they are in direct communication with the fluid of the sub-arachnoid space as well as of the spinal cord. Any impression, therefore, made upon these fluids must be made upon the labyrinth and its lymph. He goes so far as to state that pathological processes may begin in the internal ear and pass into the spinal cord, and *vice versa*.

Dr. LONGSTRETH said that there had been observed failure of vision and paralysis of the facial and some of the orbital muscles, showing an involvement of the second, third, fourth, and seventh nerves, following cerebro-spinal fever. In such cases, Dr. Burnett's explanation of the communication between the inner ear and the sub-arachnoid space would certainly not account for the failure of function in the other nerves mentioned.

The PRESIDENT said he had long been satisfied that the examination of the *substance* of the nerve-centres in cases of cerebro-spinal meningitis had not been sufficiently careful. Although it was undoubted that many of the symptoms were due to pressure upon nerve-trunks, or upon the spinal cord from inflammatory exudation, he believed that many also, and especially the marked and long-remaining paralytic ones, were due, in part, to accompanying inflammation of the nervous substance.

Dr. JOHN ASHHURST, Jr., referred to the destructive inflammations of the cornea which occur in cases of cerebro-spinal fever, as rendering it probable that inflammatory changes sometimes spread beyond the meninges and implicate the nerve-centres and nerves. A case of this kind (which, however, was not at the time recognized as one of cerebro-spinal fever) came under Dr. Ashhurst's observation in 1862, and was reported to the Society early in the next year.* Paralysis existed in this case for some time before death, but at the autopsy much slighter traces of meningitis were observed than in the specimens presented this evening by Dr. Longstreth.

Dr. CHARLES H. BURNETT presented a specimen of *mycelial tube-cast of the external auditory meatus*, removed from the ear of a female 40 years of age. "She has been affected for some years with *ozæna* and hardness of hearing, but in addition to this she has had frequent attacks of sharp and sudden pain in the ear, for which she could assign no reason. These attacks endured only a day or two, and then suddenly ceased, being followed by a slight, watery, mucous discharge from the ear. It was just after the pain of one of these attacks had ceased that I examined the left ear and removed the accompanying tube-cast from the meatus auditorius. Before the removal of the tube-cast the meatus appeared lined with, and the membrana tympani covered by, a piece of wet newspaper. This homely simile will best convey to you the appearance of these parts before the removal of the fungous tube-cast.

"As I had examined the ear for another purpose ten days previously, I know that the tube-cast had formed within that time.

"By means of a pair of curved forceps, light being

reflected into the auditory meatus by means of the forehead-mirror, I seized the outer edge of the tube-cast and removed it without any pain to the patient or difficulty to myself, for this tube-cast was not adherent.

"I thus exposed the walls of the meatus and the membrana tympani to view. These parts were not extraordinarily red nor sensitive to touch or pressure. A drop of fluid taken from the auditory meatus and *immediately* examined under the microscope revealed the presence of free spores of the *Aspergillus*, and also numerous vibriones. This I believe to be the first instance on record in which these latter objects have been found in the ear of man. They might, however, *a priori*, be supposed to be present in the ear in many cases. There were no pus-cells present in the fluid-removed from the auditory meatus in this case.

"The tube-cast of the meatus is composed of mycelium richly studded with colonies of hyphens supporting large and beautiful sporangia of a brownish-yellow color. The hyphens are not septate, and there is no membrane enclosing the sporangia. Myriads of free dark-brown spores are found, with a very little epithelium, imbedded in the mycelium as well as lying on its surface.

"The thalli are septate, and here and there I detected a little spot of bright-green coloring-matter in them. The spores are echinate; but, although that is a feature of the *A. glaucus*, I think the color of the sporangia and spores might justify the conclusion that this is a specimen of *A. flavescens*.

"The treatment consisted in three instillations of a solution of nitrate of silver (100 gr. to f \bar{z} i) within the first ten days, and the repeated daily use of instillations of alcohol (90 per cent.) for one month. This continued use of alcohol or any other parasiticide is indicated in any case of a growth of *Aspergillus* in the ear, if the disease has been contracted in a damp dwelling where the patient is still living, as in this case.

"There has been no return of pain or discharge, and upon inspecting the meatus I find no appearance indicative of the presence of a fungus in the ear.

"The rapidity of the formation of the fungous tube-cast, the presence of vibriones in the meatus, and the serous nature of the discharge from the ear, constitute very interesting features in this case.

"Wreden, of St. Petersburg, as well as other distinguished observers of this form of aural disease, unite in their testimony as to the great rarity of purulent otorrhoea as a feature or a cause of this disease, whereas, from increasing data, it appears that the presence of fungi in the external auditory meatus is productive of a characteristic but scanty *serous discharge*."

Dr. BERTOLET said that the occurrence of *Aspergillus* in the external auditory canal was not very rare. He had met cases where there has been discharge from the middle ear, and the mycelium has developed subsequently, the moist surface apparently tending to encourage its growth. He did not think that much importance could be attached to the presence of vibriones, though he is not aware of having seen any under these circumstances. He had often seen them in pus removed from the ear.

Dr. JAMES TYSON exhibited for Dr. KNIPE, of Norristown, Pennsylvania, *two concretions removed from the appendix vermiformis* of a gentleman aged 25, which had caused fatal peritonitis. The history was as follows:

For nearly a year past the patient had suffered occasional severe attacks of abdominal pain, so frequent and so severe that they had attracted the attention of the family as thus occurring. At other times, however, he enjoyed fair health, and was remarkable for his bright and cheerful disposition.

On the 21st of November he went "turtle-hunting," and in the course of the day made a leap, during which

* See *American Journal of the Medical Sciences*, October, 1863, p. 401.

he said he felt something give way, as if within his abdomen. He did not complain until Sunday morning, when he mentioned that he had pain in his stomach, which kept on increasing until evening, when he consulted his physician, Dr. Knipe. The doctor gave him two grains of morph. sulph. in four powders, of which he took three during the night without relief.

On the next day, Monday, he began to vomit. His bowels were moved that night by two doses of calomel, gr. x each, and again on Tuesday morning. The symptoms of peritonitis, however, became more marked, and he died on the morning of Friday, the 28th of November.

The post-mortem examination was made the following day. The omentum was firmly glued to the pelvic viscera, and on raising it a large amount of pus was found in the pelvic cavity. The viscera here were all firmly adherent, and on seeking the appendix it was found sphacelated, and dilated to the diameter of one-third of an inch. In it were felt, rolling under the finger, two concretions,—a larger, cylindrical, and a smaller, nearly round. On opening the gut, the former was found to be a perfect cylinder, about three-fourths of an inch in length and one-third of an inch in thickness; the latter was irregularly round, and less than one-third of an inch in each direction. They were solid, but compressible, and could have been crushed beneath the finger. On section they seemed to be made up throughout of solid fecal matter, without anything in the centres comparable to a nucleus. The appendix, from its origin in the cæcum, was permeable to an ordinary full-sized probe, and, as stated, became dilated as the vicinity of the concretions was reached.

Dr. TYSON thought the previous history of the case explained most satisfactorily the conditions found. These concretions had evidently been forming some time, causing the occasional attacks of severe pain from which the patient had suffered throughout the year, and which were the result of attacks of limited local peritonitis. These were sufficient to produce adhesions, and it was one of these which was ruptured in the leap referred to, and thus became the starting-point of the final peritonitis, of which he died.

Dr. WILLIAM PEPPER presented a specimen of *perforative disease of the appendix vermiformis and ileum*, from a case in the practice of Dr. J. R. F. BELL. The patient was a vigorous lad of 17 years of age. There had been no symptoms of intestinal disease before this attack, which had followed violent over-exertion. The early symptoms were severe pain in the right iliac region, and frequent and violent vomiting. The bowels were moved on the third day by enemata, though the fecal matter probably came only from the colon. The symptoms were much relieved at first by opiates. No free evacuation of the bowels, however, occurred. Extreme soreness and distention of the belly continued, and on the fifth day vomiting recurred, and soon became fecal. No tumor could be felt at any time. The urine was at first scanty, and passed frequently and with effort; but later it became abundant, and was passed easily. The vomiting was a second time relieved by opiate suppositories and exclusive feeding by the rectum, and the stomach soon became retentive, and continued so until the end. No evacuation of the bowels was obtained either by enemata or repeated laxatives, and the obstruction seemed to have become absolute. The distention of the belly increased until the coils of enormously-distended bowel could be readily traced through the thinned abdominal walls.

Death occurred, in a state of extreme prostration and emaciation, on the tenth day of the disease.

Autopsy.—Abdomen alone examined. The small intestine was enormously distended down to 18" above the ileo-cæcal vulvi. At this point there was a firm,

sharp edge of mesentery, belonging to a fold of ileum which was twisted on itself, which compressed the bowel against the right side of the vertebral column, so as entirely to occlude it. The remaining part of the ileum was empty, and pressed into a small, lead-colored mass against the right sacro-iliac synchondrosis. On following it down, a perforation of the ileum was found $1\frac{1}{2}$ " above the valve. The ulceration of the serous coat was fully 1" in diameter, while the perforation of the mucous membrane was not more than $\frac{1}{2}$ " in diameter, so that evidently the progress of ulceration had been from without inwards. The appendix vermiformis lay directly across this ulcer. For the first $1\frac{1}{2}$ " of its length it was adherent to the cæcum, its walls were thickened, and its calibre patulous. At that point, however, ulceration had occurred to such an extent as entirely to sever the appendix. The detached part was about $1\frac{1}{2}$ " long; its walls were thin and dilated, and presented two ulcerated perforations. It contained two concretions, one $\frac{1}{4}$ ", the other $\frac{1}{8}$ " in diameter, formed of inspissated mucus. This part of the appendix was connected with the proximal part only by some shreddy connective tissue. There was a small quantity of sanious pus mixed with fluid fecal matter which had escaped from the ileum, but no attempt had been made at the limitation of this and the formation of an abscess. Some of these fluids had flowed into the pelvis. The general surface of the peritoneum was dark, intensely injected, and dry, but there had been no exudation.

Remarks.—Among the points of interest about this case may be mentioned the latent existence of two concretions in the appendix, and the active symptoms excited by excessive muscular straining. The symptoms indicated two phases of the case,—the first due entirely to ulcerative disease of the appendix and ileum, and the second, which began on the fifth day, due to the perforation of the ileum and the occurrence of a twist of the bowel, entirely obstructing its calibre.

Dr. L. A. DUHRING desired to know the exact composition of these concretions. He had seen but a single case, which occurred many years ago in his own family, before he had any knowledge of medicine, but he recollected seeing the concretions.

Dr. LEONARDO S. CLARK alluded to a concretion which had been examined by Dr. James Tyson two or three years ago, in which a collection of hair had been the nucleus, and another in which a cardamom-seed had served the same purpose.

The PRESIDENT said that a great variety of objects had been found as nuclei, such as gall-stones, small intestinal worms, foreign bodies which had been swallowed, as small seeds, beads, and the like. In many instances, however, the body found in the appendix was named from some fancied resemblance, as to a cherry- or date-stone, while in reality they often are mere concretions of inspissated mucus or fæces. Even when there is a nucleus of some foreign body, concentric layers of inspissated matter usually have formed around it.

Dr. CLARK said that in both of his cases there was intense pain in the genital organs; one being that of a young girl of fifteen or sixteen years, the other that of a man of twenty-one. The pain in both instances was so great that the friends of the patients spoke of it. He had recently been reading in a Western journal the report of cases in which this symptom was also mentioned by the reporter.

Dr. JOHN H. PACKARD said that in January, 1861, he presented to the Society a concretion which had lodged in the appendix vermiformis of a boy eleven years old. He did not now recollect whether there was a nucleus or not, but an abscess of considerable size had formed about the appendix, which was perforated.

Dr. TYSON also exhibited the *heart and kidneys* of a

man aged 51, who was admitted to the medical wards of the Philadelphia Hospital about the 1st of November, with a double aortic murmur, dyspnoea, dropsy, bloody and highly albuminous urine, which contained also casts filled with broken-down epithelial cells, granular casts, and casts containing blood-corpuscles. He had been for many years an attendant about the hospital, and was very intemperate. He died within a week after admission, previous to which, however, the albumen and blood had greatly diminished. On post-mortem examination there was found extensive disease of the aortic valves, which were stiff with calcareous deposit, while the aorta was atheromatous as far as examined, which was several inches from its origin.

The *liver* was cirrhotic, hob-nailed.

The *kidneys* were simply turgid with blood, and weighed, therefore, somewhat more than in health, but were not otherwise enlarged; and their minute structure exhibited slight increase in the interstitial connective tissue.

The case was interesting chiefly in the relation of kidney- to heart-disease. Here the aortic disease was so advanced and the condition of the kidneys so slightly changed that there could be no doubt that the cardiac disease was primary, while the man had, at the time of his admission, all the symptoms of an acute nephritis. The latter was probably due to the direct influence of cold upon an organ already congested, but not otherwise the subject of extensive disease.

Dr. TYSON also exhibited the *spinal cord* from a case of *progressive locomotor ataxy*. There was extensive softening throughout the entire thickness in the lumbar enlargement, while higher up there was also a wedge-shaped segment of sclerosis involving the antero-lateral column for one and a half lines on each side of the anterior median fissure.

Dr. TYSON also exhibited a specimen of *abscess of the liver*, without history.

Dr. J. SOLIS COHEN presented a specimen of *subglottic multiple mucous polypi of the larynx*, removed with lateral forceps. Adam B., æt. 30, was sent to the doctor December 6, by Dr. Webb, of this city, on account of persistent hoarseness of over four years' duration. The general health was good, and the hoarseness the only symptom of disease. It had apparently resulted from catarrh due to exposure while the patient was on the police-force,—the voice having been much used previously in the business of huckstering. The voice had that peculiar dysphonia usually indicative of morbid growth in the larynx.

"On laryngoscopic examination, a large morbid mass was seen beneath the left vocal cord, reaching beyond the right cord, and projecting above the glottis with every expiration. I thought it was a papilloma, and so informed Dr. Webb, inviting him to attend with the patient the next day, when I would make an attempt at removal. On the following day I demonstrated the growth to Dr. Webb, and immediately afterwards introduced the forceps and removed a large portion of the growth. Examining this more closely half an hour after with Dr. Bertolet, it appeared that this growth was a distinct single polyp, partly mashed in the teeth of the forceps.

"On the following day I removed in the same manner another growth, similar in character, but also mutilated by the forceps. On examination, I was somewhat surprised to see a third growth still in the same situation. This I removed on the following day, and it was fortunately so seized as to be preserved intact.

"All these growths were pedunculated, and were attached in close approximation, apparently, to the anterior portion of the thyroid cartilage, just below the glottis and to the left of the middle line.

"The chief point of interest in the case is in the mul-

tipile nature of the growths, which, though frequent in mucous polypi of the nasal passages, is rare in those of the larynx; and another point, of less interest, is in their location.

"This is the first case of multiple pedunculated polypi that I have seen out of more than one hundred cases of laryngeal growths, and only the second of that kind that I have removed from below the glottis.

"This form of tumor is fibro-cellular, is comparatively rare in the larynx, existing in only about five per cent. of the cases of laryngeal growth; and its usual seat is upon the epiglottis or upon the vocal cords.

"If the growth is myxomatous it is still more rare; myxomata occurring in not more than five-tenths per cent. of the whole number of laryngeal growths."

The specimen was referred to the Committee on Morbid Growths, which reported: "The laryngeal tumor extirpated by Dr. Cohen is deemed by your committee to be a *myxoma*. The cells which are abundantly present in the hyaline ground-substance are mostly stellated, and frequently anastomosing; others, again, are without any processes, being nearly round. The microscopic section shows that the growth is distinctly lobulated, due to the coarse septa of ordinary connective tissue. In the latter only were any blood-vessels detected, these all presenting a very wide lumen."

GLEANINGS FROM OUR EXCHANGES.

THE CONSTITUTIONAL RELATIONS OF SECOND DENTITION (*New York Medical Journal*, January, 1874).—Dr. Joseph Mulreany, in an extremely interesting paper, records a number of cases occurring in his practice, and illustrating some practical points connected with the protrusion or cutting of the permanent teeth, especially the first four molars and the four wisdom or third molars. He believes that the physiological irritation of a new tooth cutting through the gum is the direct, though frequently unsuspected, cause of many diseases, both of childhood and maturity, and that the results of treatment demonstrate conclusively that such is the case. He says that every case of true morbus coxarius he has met with began between the fifth and seventh year, or it might be a few months earlier, and also whatever mischief occurred to the joints took place during the cutting of the first four molars of the permanent teeth, and that after they had come fairly through the process of separation commenced. His illustrations are numerous, the more important ones being as follows:

Case I.—Miss W., when a child of between five and six years, suffered from morbus coxarius. The first indications of the joint-disease were lameness and pain when the head of the femur was strongly pressed against the acetabulum. In process of time the usual symptoms of pain in the knee, flattening of the hip, and shortening of the limb, took place, but all in a mild form, and all subsided at the end of her sixth year, coincident with the complete protrusion of her first four molar teeth, leaving her slightly lame for life. She was a member of a family of a highly scrofulous diathesis.

Case II.—Margaret McC., aged 6½ years; had had pain in the left hip-joint and knee for over a year; slightly lame; hip flattened; right upper molar still to be protruded. The gum was well scarified, and she was ordered iodide of iron with senna as an aperient,—the gum to be scarified once a week until the tooth came fairly through. In a month she was greatly improved.

Case III.—C. D., æt. 20 months; had enlarged and suppurating cervical glands, but was in good condition. About the twenty-fourth month he had cut all

his deciduous teeth, and every bad symptom disappeared. In his fifth year he was suddenly seized with pains in his left hip. He was ordered an effervescent mixture containing iron and iodide of potassium, and a small blister was applied from time to time over the hip-joint. The gums were not scarified, owing to the violence of the patient. This condition continued for a year and a half; sometimes he could walk without the aid of a crutch, but invariably, when he had a teething-spell, he was forced to crawl about on all-fours. At this time a surgeon, who was called in consultation, diagnosed such an amount of disease as to warrant immediate resection of the hip-joint, though Dr. Mulreany was convinced that it was a case of morbus coxarius brought into action by dental irritation. An amputation of the head of the femur was attempted, but a deep and ample incision down to the capsular ligament assured the operator that the joint was too sound to justify him in cutting into it. The operation was abandoned; but the final issue of the case is not stated.

Case IV.—A boy, æt. 6 years, was seen in consultation. His physician stated that for six weeks the boy had had a kind of remittent fever, worse at night, with obstinate constipation. On examination, it was found that the first four molars were pressing against the gums, causing much tension, and that there had been epistaxis. A few days later, the child growing worse, the gums were scarified, a laxative mixture was given, and in two days the attack was concluded.

An important medico-legal point sometimes arises between the eighth and fifteenth year, the inflamed condition of the gums over the bicuspidis often giving rise to a purulent discharge from the vagina. The English law treats all illicit sexual intercourse with females under sixteen years of age as rape, and too often such discharges have been received as testimony of the fact.

Of the phenomena associated with dentition between the seventh and fifteenth year, scrofula of the bones, nocturnal incontinence of urine, chorea, and heart-affections are the most common.

Now in regard to the wisdom-teeth:

Case VII.—Mr. V., æt. 23, subject to violent bilious attacks, low-spirited, sleepless, constipated, frequent epistaxis, pain in articulations of lower jaw. None of the wisdom-teeth through. His gums were scarified, and he was ordered to do the same frequently, and to take a little tincture of iron and an infusion of senna. Cured.

Case VIII.—Miss A. D., æt. 18; tall, fair, anæmic, cardiac bruit, violent headaches, profuse epistaxis, irregular menstruation; wisdom-teeth not quite through. Her gums were thoroughly scarified frequently, and quinia and tincture of iron, with senna, as an aperient, were given. Cured.

Case IX.—Miss B., æt. 20; profuse epistaxis, preceded by jaw-ache, approaching phthisis of right lung, quick pulse, loud anæmic cardiac bruit, amenorrhœa, frequent micturition, constipation. Wisdom-teeth had not shown themselves. Her gums were scarified, and she was ordered quinia, iodide of iron, and tincture of digitalis.

Case X.—Miss S., æt. 17; pale and exsanguineous, palpitations of the heart, headaches, constipated bowels, menorrhagia, coated tongue, chlorotic bruit. She had lost great quantities of blood, owing to nervous obstruction at the centre of the circulation, caused by dental irritation from the wisdom-teeth acting directly on the heart. Scarifications, iron, and digitalis effected a speedy and perfect cure.

Case XI.—Mrs. J. M. S., æt. 19; married six months, during which time she has had a colored discharge from the vagina. None of the wisdom-teeth present. Scarifications and tincture of iron gave the happiest results.

Dr. Mulreany proceeds to state that dental irritation

may be the cause of dropsical effusions, both in the chest and abdomen, of heart-affections, of hysterical troubles of the joints, of masturbation, and of sterility and miscarriage, and gives cases in support of his views; but he asks that the physiological irritation of which he speaks shall not be confounded with the pathological irritation of an old, decayed, and carious tooth producing periostitis and gum-boil.

MISCELLANY.

ANALYSES made of beer-yeast and cobra-poison are said to have proved these two substances to be exactly identical in chemical composition. Such an announcement will be a veritable godsend to the anti-bacchanals, with whom it is a favorite device, when bemoaning the follies of their benighted brethren, to exhibit a bottle containing a disagreeable-looking fluid declared by them to be fourpenny ale from which the spirit has been eliminated. The teetotallers, who, like the law, take no notice of extreme trifles, will probably, in their great joy, "overlook the fact that minute quantities of other elements may be present in the yeast and poison respectively, although they elude the grasp of the chemist;" sufficient for them that the same respective quantities of carbon, nitrogen, oxygen, sulphur, and hydrogen are contained in beer-yeast as in the poison of the cobra.—*Food Journal*.

POISONOUS UNIVALVES.—Seven individuals who had eaten snails at dinner were, so says the *Montpellier Medical*, affected with sickness, diarrhœa, giddiness, fever, etc. No doubt could be entertained as to the cause of the poisoning. The seven persons had all eaten of the snails, whereas they had not all eaten of the other dishes served up at the dinner. The pan in which the snails had been cooked was in perfect condition, and had been freshly tinned. The poisoning, therefore, took place through the snails themselves. It is well known that they often feed on poisonous plants, such as belladonna, digitalis, and hemlock, and on the fields from which the snails had been gathered were found boxwood, euphorbia, and prickwood. It is on account of this that snails gathered to be eaten are generally submitted to a few days' previous fasting.—*Food Journal*.

AFTER a brief life, the *Canadian Medical Times* has passed out of existence, as a child born out of due time. The mania for losing money in medical journals still continues, however, and we have just received the first number of a new bi-monthly, the *Vermont Medical Journal*.

NOTES AND QUERIES.

As Centennial news and reminiscences are at present the rage, we print the following letters, for which we are indebted to Dr. Walter F. Atlee: they show what kind of intermittents they had in the good old times. Mrs. Cox was the wife of Colonel Cox, the intimate friend of Mr. Reed, of Revolutionary memory.

"BURLINGTON, 3d October, 1776.

"MY DEAR FRIEND,—As you must have heard by Mr. Cox of my afflictions in the sickness of my children, so I take the first opportunity

in my power to communicate the happiness I feel upon their recovery. I know you'll partake a parent's joy in seeing a beloved child restored to life after all hope was fled—that child nearly arrived to the age of woman, & just discovering what the woman would be, & to do her justice, she was what we wished her to be, a few things excepted, which time, I doubt not, will rectify. To see her in violent convulsions for thirty hours, near which period she seemed breathing her last, was almost too much to bear. She had, as well as the rest, the intermitting Fever, tho' indeed hers did not intermit at all for 17 days, only remitted when she was suddenly seized with a fit, which lasted as above mentioned, when she gradually & insensibly fell into a sound sleep which lasted thirty Hours more, during which time she never spoken nor showed any signs of reason. The fourth day her recollection returned, and also her feeling of the sorest Blister I ever saw. This day is a fortnight since the fits came on, and she is now able to sit up in her Chair good part of the day. Little Molly is well; she was the only one that escaped the Fever. The others are in a fair way now; indeed, Kitty seems quite well. What a favor I esteem it that I have kept well & able to nurse them! I have had five at a time down in the Fever. One of my maids was taken a few days ago; she is very bad. I hope tho' soon to have the pleasure of saying we are all well again. Can I enough admire the goodness and the Power of God? He brought my first-born to the brink of the grave, & then restored her as a new gift me. Surely her Life is preserved for some valuable purpose. Oh, may she improve these added years in the service of her Maker, & may I have a thankful Heart for all His favors. I had to send for Mr. Cox from the Furnace. The shock was almost too much for him. I never saw him in such distress; I was forced to try to forget my own sorrow to comfort him. But the Almighty has been pleased to comfort us both in returning to Life our Child. I know you will excuse my dwelling so long on this subject, but I will now change it, & wish I could give you any information of our Friends to the Eastward, but not one word have I heard from them these several months. I intend to try if I can get a Letter answered by the Post; I think through Mr. Reed I may. Mrs. Reed was yesterday Deliver'd of a Daughter. Poor little woman! she has much to struggle with. Mr. Reed has a dangerous Post, & his absence at this time is peculiarly distressing. He has had three narrow escapes for his Life: his Horse Shot under him; he only left a House five minutes before the regulars were in Possession of it, & in endeavouring to make a flying Lieut. return to his Duty the man Level'd his musket at him, which luckily flashed without going off. He was try'd and sentenced to be shot, when upon the day of execution everything was prepared with the greatest solemnity, the man was upon his knees expecting the Ball. The general was prevail'd upon to Pardon him, which so overcame him he had like to have Died with the joy. This I had from Mr. Montgomery, who was present. As to news, I can tell you none but what the Papers will convey before this reaches you. I believe they are in daily expectation of a Battle. What a dreadful Fire there has been in N. York. Oh, this war! What Devastation does it make! Where or when will our troubles end? The Cloud is darker, methinks, than ever, tho' the Politicians don't think so or won't say so. Oh, Sweet Peace, when wilt thou bless our Land again? "I have not heard from you in a long time; pray write soon, and be assured that however I may be taken up for a time with my own affairs, I am no less than ever your truly affect. friend & Sister,

"E. Cox."

"BATSTO, January 6, 1777.

"MY DEAR FRIEND,—Various have been my places of abode since last I wrote to you. I was hurried from Philadelphia at an hour's warning; pack'd up and sent off chief of my goods the same day I got home, but as the enemy was no further than Brunswick, I prevail'd upon Mr. Cox to let me stay with the family and such things as we could not do without till the necessity was greater for moving; I could not bear the thought of being where I could not hear from him; he left me and join'd his Batt'n at Trenton, but they were soon oblig'd to leave it, & recross the Delaware. He wrote me from there to go off immediately, as the enemy would probably be down our side of the river, & so it proved; the day after we left Mount Holly the Hessians were in it. I did not care to come here lest the Furnace might draw them to destroy it, as they were told it had been making ball during the war. I was in a great strait where to go. If I could have got over to Pennsylvania I should certainly have gone to Lancaster, but Teams were not to be got there; here we had them plenty. I fix'd half-way between Burlington and this place. I had not been there a week when I was inform'd by good authority that they had been within three miles of me. I then for the first time lost my courage; for an hour or two I was completely wretched. The manager of the furnace, who had been my helper through all the difficulty of moving, was gone to philada. I was on the roadside & had all my valuable effects in the house; I recollected that desponding was not the way to deserve help; I therefore

sent immediately for a team, loaded it with my best things and sent it off. In the evening the manager came. Mr. Cox sent off an Express to me to go from there without loss of time, & not content with that, ventur'd to come himself in the night at a great risque to hurry me away. By ten o'clock the next day our waggons were all loaded, and we sat off, intending not to have stop'd more than a night here, but to have gone many miles further; but my poor Rachel was taken ill again, & I was oblig'd to return with her to our friends—who had taken a Large house a few miles from where we were, in a by-place, where they continue still. I mean Mr. Pettit and Mrs. Reed, who had join'd families—in a few days she got better & we came here, & hearing the Enemy did not come further I ventur'd to stay, & now have the happiness to hear our Army has drove them back. Oh, may the God of Battles grant them further Success, & make our Enemies fly before them! How is my heart torn with conjectures of the fate of my other self; he was in the Battle of last thursday, at trenton, and was well afterward, but how he fared in the one at princeton the day after, God only knows. I am a miserable being at present, and shall not be otherwise till I hear of his safety. You can have no Idea of the Scenes that are every day exhibited in this part of the world—barns burnt, fences torn up, cattle drove off, women & children used ill by the Hessians when they ask for a thing and are answer'd, they have none; the bayonet is presented to their breasts, & go & get it then, is the reply, with some smart strokes of a Hickory. This I was told by a gentleman in whose house they had taken quarters, and they oblig'd him to keep two men attending the fire all night; they would not fetch themselves a stick of wood, but said the rebels should wait upon them. Many other instances I could relate that would shock you. I have seen several people that have been among them—some who got their protection. The Head Officers behaved polite, but the under ones & the soldiers most barbarously; in some houses they did not leave even a Child's petticoat nor any one wearable unstoln. I should have wrote you before, but have had a bad whitlow on my thumb; indeed, writing is my only amusement. I have receiv'd many favors from my Burln friends, and have been under a necessity of writing a good deal to beguile the tedious hours by it, & if I could receive a line from you it would help me to bear this Exile with patience. I will not further enumerate the troubles I've gone through; your sympathizing heart will too sensibly tell you. Peace has ever been my most ardent wish; it is so still could it be upon honorable terms. I think it might be obtain'd, but I am no politician. I must leave these matters, & can only now add my best respects to your good man and family. Two of my children are still unwell. Adieu.

"Your friend,
"E. Cox."

We thank the profession for the liberality with which they have responded to the appeal for aid in building a monument to the memory of the Memphis physicians who fell a victim to yellow fever, and acknowledge the receipt of one dollar each from Dr. S. Littell and H. C. W., Jr.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

IN reading the *Times* of January 17, I find a criticism on my article on "Hymen," published in a former number. Now, I would say in answer to Dr. Bernardy, that the case was in every respect as I reported it, but I should have stated that the hymen gradually gave way under pressure until it did not offer much resistance to the passage of the child's head although it is probable that fibres of the membrane were ruptured, and continued to give way until dilatation was sufficient for the child to pass. And it is possible that rupture may have taken place after the membrane became dilated, and was unnoticed. I thought dilating preferable in this case to incising, as it is less liable to produce hemorrhage. Ramsbotham, in his work on Obstetrics (page 248), says of the treatment of these cases, "The aperture must be dilated if possible by mechanical means." So it is not thought impossible for a hymen to be dilated sufficiently for labor to be completed.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 20, 1874, TO JANUARY 26, 1874, INCLUSIVE.

GIBSON, J. R., ASSISTANT-SURGEON.—Granted leave of absence for forty days. S. O. 2, Division of the South, January 20, 1874.

TAYLOR, M. K., ASSISTANT-SURGEON.—Assigned to duty at Fort Stockton, Texas. S. O. 8, Department of Texas, January 15, 1874.

SATURDAY, FEBRUARY 7, 1874.

ORIGINAL COMMUNICATIONS.

DIFFERENTIAL DIAGNOSIS BETWEEN PSORIASIS AND SYPHILODERMA SQUAMOSUM (SO-CALLED PSORIASIS SYPHILITICA).

BY LOUIS A. DUHRING, M.D.,

Clinical Lecturer upon Diseases of the Skin in the University of Pennsylvania, and Physician to the Dispensary for Skin Diseases, Philadelphia.

THE diagnosis between these two diseases is so often attended with difficulty that I shall, in the present communication, make the endeavor to separate the two conditions clearly and show wherein they essentially differ. Psoriasis and the squamous syphiloderm are both sufficiently common in a large community, the former disease, however, being unquestionably of much the more frequent occurrence. It is an affection which, when typical, possesses features highly characteristic and familiar to every one who has had opportunity of observing even a limited number of cutaneous diseases. I shall therefore not enter into any description of its characters here. I may, however, briefly state that it is a distinct cutaneous disease; with a definite and well-marked set of symptoms, the majority of which are almost always present. It is one of the most clearly defined of all the affections of the skin, standing forth conspicuously alone among the many other processes. Although it may coexist with other diseases of the skin, that is, be present while another affection of a different nature is at the same time running its course, yet it is never in any manner altered, but on the contrary always maintains its peculiar features intact. It never mingles or blends with other cutaneous affections thereby becoming disguised or unrecognizable. Psoriasis once, psoriasis always.

Syphilis of the skin likewise possesses many well-defined and unmistakable symptoms, but the varieties and forms of eruption are manifold, and require most careful consideration and diagnosis. They are not, however, involved in unintelligible darkness, but show themselves as a group of pathological lesions which, when once recognized, offer no further embarrassment. But it must be remembered, as stated in a recent lecture,* that these lesions are syphilis pure, unmingled with any other disease of the skin; they are the evidences of syphilis alone, and must be so estimated. For instance, with the squamous syphiloderm, the old so-called "psoriasis siphilitica," the only disease present is syphilis; although it might seem perhaps, from the term, as indeed has been represented by certain writers, that a trace or more of psoriasis existed. In brief, without entering into the subject further, I would state that psoriasis and syphilis are entirely separate diseases, and are never, under any

circumstances, influenced the one process by the other.

To a close observer there are many points of difference between a true psoriasis and a squamous syphiloderm, many of which, with attention and a certain amount of skill, can readily be distinguished and made available for diagnostic purposes. Some of these dissimilarities may, however, at times be slight or almost imperceptible, and this fact must not be forgotten when called upon to decide the diagnosis. As typical examples of any of the cutaneous diseases are exceptional and rare, it must not be expected that all of the characteristic signs of either of the two diseases under consideration will at any time be present. The fact also must be borne in mind that the diagnosis between psoriasis and syphilis is in reality one of the most difficult and delicate tasks in dermatology, demanding all the skill and power of observation which the student can command. The diagnosis often rests upon very slight variations. Errors in diagnosis between these diseases are common, nor indeed need this be a matter of surprise when we consider how trifling the difference must often appear to an unpractised eye. In speaking thus, it must be understood that we are dealing with objective symptoms only, those symptoms which the skin presents to the eye.

When a case offers itself for diagnosis the following points must be regarded:

Age of the patient.—Psoriasis is an affection which frequently manifests itself in childhood, at times as early as the sixth year, and remains with the individual to a greater or less extent for an indefinite period, at times months, but more commonly years. It is often seen in children at about the age of puberty. The most usual period for its first appearance, however, is in early adult life, at the age of twenty or thereabouts. It occurs also later in life, and in fact may first show its presence at any time from early childhood to old age.

Inasmuch as *acquired* syphilis is rare before adult life, we do not expect to find the squamous syphiloderm until this period. *Acquired* in contradistinction to *congenital* syphilis is here meant, these two terms being employed to denote respectively syphilis which has been obtained after the birth of the child and that which has been gotten in utero. As is well known, congenital syphilis also gives rise to a series of cutaneous manifestations, but if we except certain of the syphiloderms of infant life, it rarely if ever in later years produces any lesions resembling psoriasis. The squamous syphiloderm then is almost always confined to adult life and is the result of acquired syphilis.

Hereditability.—It not infrequently happens that we have an account of psoriasis being handed down from parent to offspring. At the same time I am inclined to think this transmission less common than is ordinarily believed. It is, without doubt, however, one of the diseases of the skin which may be transmitted from one generation to another.

There is no history of hereditability with the squamous syphiloderm. It may then in brief be

* Clinical Lecture upon a Papulo-squamous Syphiloderm, by the writer. *Philadelphia Medical Times*, No. 112.

stated that psoriasis is at times hereditary, but that the form of syphilis under consideration is never so.

Previous history.—In connection with a squamous syphiloderm there is usually some clue to the initial lesion, to the inoculation of syphilis. If this is not to be obtained, there is in most cases some account of subsequent or secondary symptoms, which it will be possible to elicit either by cross-questioning or by gaining the confidence of the patient. For this variety of syphilis is not one of the early exhibitions of the disease, but, on the contrary, is one of the late forms, showing itself six months or more and even years after the chancre. But too much stress must not be placed upon the history, for at the present day clinical experience teaches how serious errors are often incurred by relying upon the record of a patient. Observation has convinced me that many individuals have syphilis who have no idea that they are the possessors of this disease; much less do they know in what way it has been contracted. History here is of little value.

On the other hand, a clear and positive history of psoriasis is usually obtainable, especially if the patient have had the trouble for some time. The account of one attack of psoriasis is generally very similar to another, and it will be observed that patients give their story in a stereotyped and almost characteristic way.

Duration of the disease.—Psoriasis may continue for months or years, annoying the individual intermittently; or, in exceptional cases, it may remain present continuously for an indefinite period. The tendency of psoriasis is to recur at intervals through a lifetime. Occasionally it entirely disappears, and then suddenly bursts out again with full vigor. Relapses are the rule, particularly where the cure has resulted from external treatment alone. They may occur as often as several times in the course of a year. The great majority of patients who have been affected with psoriasis for some time will remark that they have had many relapses. A return of the disease does not necessarily show itself in the old locality, but may occur anywhere upon the skin.

The squamous syphiloderm, though very persistent and stubborn in its course, when once entirely removed by treatment, is not apt to return. It may last months or years, and, if only partially relieved, tends to relapse similarly to psoriasis. If some of the disease still remain when treatment ceases, it is prone to show itself again in the same place. The duration of the disease, therefore, must be accepted guardedly as being at all diagnostic of either affection.

General health of the patient.—The condition and general appearance of the patient will usually be of assistance in diagnosis. Exceptions there are here also, but, as a rule, psoriatic persons, and especially adults, bear unmistakable evidence of apparent good health. They are for the most part properly nourished; are well formed and developed in frame; are often stout and robust, with between the patches of psoriasis a clear, florid skin which has the look of typically sound tissue. The appetite is good, the functions of the body are usually in order, and

the individual appears to enjoy more than average fair health, with the exception of his skin trouble, and even this does not generally worry or harass his mind to any extent.

Now, it will be noticed that those suffering from a thorough absorption of the syphilitic virus, and this condition may be inferred whenever the squamous syphiloderm manifests itself, universally show signs of this saturation affecting the health. Their general condition is more or less involved, and very often in so marked a degree that syphilis seems stamped upon their physiognomies. The countenance has lost freshness and tone, and in place a sallow, dark hue pervades the face. The skin of the whole body is similarly changed and has parted with its normal, healthy tint. The patient likewise does not possess natural vigor or force of mind; he is indifferent, downcast, and perhaps hypochondriacal. The health is impaired, and nervous depression with other symptoms is not infrequently present. The contrast here to the general good health of the average psoriatic patient is usually striking.

Form of the disease.—Referring now merely to the *contour* of the eruption, psoriasis almost invariably assumes some definite pattern or outline. This uniformity of figure is quite constant, deviating only when the disease is very extensive and one patch has been merged into its neighboring companion. The form may be either round, varying in size from a pin-head to several inches in diameter, or in the shape of bands, running here and there, particularly over the region of the chest and back, forming elliptic curves or festoons. This latter form is also encountered in syphilis, but usually to a more limited extent. In psoriasis, however, whatever be the pattern assumed, it is everywhere the same. The form adopted in one part of the skin is seen wherever the disease exists upon the individual, whether it be the circular or linear form.

The patches of a squamous syphiloderm have no very definite tendency to form into a regular system of contour. They may take upon themselves any pattern as to outline and vary their shape according to locality or circumstance. There is, however, one peculiarity of form which, from the frequency of its appearance, must be regarded as more or less characteristic. This is a tendency to assume a semi-circular figure or the shape of a segment of a circle. If papules be present in any number they will invariably tend to group in this way. This form is more common upon the arms and extremities, or, where the disease is limited in extent.

Edges of the patch.—If the border of a patch of psoriasis which has been denuded of scales be inspected and examined carefully with the finger, it will be noticed that there is no abrupt line or edge present, but that the surface gradually fades away into the sound skin, without perceptible line of demarcation.

In the syphiloderm the patch is usually elevated and possesses a marked and raised line of limit. The disease does not glide imperceptibly into the healthy skin, but terminates abruptly. This border may often be detected by passing the finger over its surface. It is the line of the plastic syphilitic

deposit. When it invades the palm, it is less definite than upon other parts of the body. The edges here are only slightly raised, but are ordinarily encircled with a film-like, shrivelled scale. In psoriasis the elevation of the patch is due to the scales, which exist in such quantity. If these be thoroughly removed, we come at once upon a red, shining surface, not much, if at all, elevated above the level of the surrounding healthy skin.

Symmetry.—Psoriasis has a decided tendency to occur symmetrically upon the various regions of the body. When present upon one side, it is the rule to find it on the corresponding part. When existing upon one limb, it is usual to find it upon the other.

This observation does not apply to the syphiloderm, for rarely do we find that it disposes itself with any degree of symmetry, excepting in connection with the palms or soles, and even here it is subject to variation.

Regions of the body involved.—No part of the skin possesses immunity from psoriasis. The same remark applies equally to syphilis. At the same time, there are certain lines which experience enables us to draw, and which may be here referred to. Psoriasis inclines to involve a large portion of the surface at the same time. The squamous syphiloderm rarely does.

Psoriasis is an exuberant product. Syphilis is apt to be scant. Psoriasis attacks remote parts of the body at the same time, as for instance, the head or upper extremities and the lower limbs, or, the whole skin at the same time may be the seat of the disease. A favorite locality for psoriasis to make its appearance is upon the elbows and knees. If it occur upon either the knees or the elbows it is apt to appear upon both knees or both elbows simultaneously. In a large number of cases it is present, to some extent at least, upon the localities just referred to. The disease is prone to make its first appearance here.

The syphiloderm generally confines itself to one portion of the body. The upper and lower extremities are not often affected at the same time. The amount of surface involved is usually small and limited in extent. Although it is the exception to see large tracts of skin attacked, nevertheless occasionally the disease spreads extensively, forming patches the size of a hand and much larger.

The syphiloderm rarely occurs upon elbows or knees; still more rare is it to find these regions symmetrically affected. With the exception of elbows and knees, psoriasis has no predilection for any particular portion of the body, and is as frequently seen upon various parts of the trunk as upon the extremities, and vice versa. The syphiloderm inclines to show itself on certain portions of the body rather than upon others. It is more commonly seated upon the chest and abdomen, about the shoulders and arms, upon the forehead and scalp, and upon the palms and soles.

Palms and soles.—Both psoriasis and syphilis may attack these regions. Psoriasis may appear exclusively upon either the palms or the soles, the rest of the body remaining entirely free. In like

manner syphilis may show itself upon either the palms or the soles, no other symptom of the disease being anywhere else present. The syphiloderm may also appear upon both palms and soles; upon palms or soles alone; or, as is often the case, upon one palm or one sole alone. When psoriasis invades the palms or soles, it is usual to find it upon other portions of the body at the same time. When syphilis attacks the palms or soles, it is the rule to find no trace of it on other parts of the skin. It is not uncommon to find either disease upon one palm or sole only.

First symptoms.—Psoriasis may be attended with certain acute and inflammatory symptoms, for example, itching, tingling, burning, and other disagreeable sensations. Itching, to a greater or less extent, is generally present with psoriasis. This symptom is often especially annoying at the commencement of the affection.

Some itching may also exist with the syphiloderm, particularly if located upon the trunk; but it is never sufficiently active to cause the patient to scratch; nor is it at all comparable to that of psoriasis. A beginning syphiloderm does not itch, whereas, as just remarked, a commencing psoriasis generally does. Psoriasis is usually an active disease in its early development and progress. It not infrequently extends rapidly, and in a short period may occupy a great portion of the skin. Syphilis on the other hand increases its area step by step and at times extends very slowly.

Pathological characters.—The pathological characters of psoriasis and syphilis are essentially different. Syphilis always manifests its presence in the form of a deposit or infiltration in the tissue. This pathological feature is always present and is very often marked. In psoriasis there is no deposit or infiltration of new material into the corium. The disease consists simply in a hyperplasy of the cells of the rete, attended with peculiar inflammatory symptoms. This difference in the pathological structure of the patches is generally appreciable even to the naked eye, and constitutes one of the most valuable diagnostic signs between the two diseases. Exclusive of the scales, there is very little thickening of tissue in psoriasis. In syphilis there is decided thickening of the skin, and it can in most cases be detected without much difficulty; it varies in degree, however, according to locality and other circumstances. Upon the palms it is least marked. It is in this region that the two diseases most simulate each other, and where diagnosis often becomes most difficult. In these cases the skin should be taken up by the fingers and delicately examined before an opinion is pronounced, for it is not infrequently by this means alone that a correct estimate of the amount of thickening present can be obtained. Attention and care are requisite in order to discriminate between the thickening due to inflammatory swelling and puffiness, and that arising from the gradual plastic deposit of syphilis.

The syphiloderm may consist of more than one kind of lesion, a variety being at times observable, composed of papules, ulcers, and scales. Papules are frequently found, and may be scattered here

and there, or, as is more generally the case, aggregated in small groups placed in semicircular form. They may be covered and disguised by thin, whitish scales; or, they may be free of scales and prominent to view. They are inclined to be rounded or flattened at their apices, and not acuminated.

Now, in psoriasis there are never any papules present. The disease always shows the same pathological characters, which are pathognomonic of the affection. A patch of psoriasis consists of a circumscribed, inflammatory, red, even surface, which is always found covered with scales.

The patch of syphilis may consist of a uniformly diffused infiltration, or it may be composed of a number of aggregated papules which have coalesced, making an irregular uneven surface, sparsely and imperfectly covered with dried epidermis.

Color of the disease.—The color of a spot of psoriasis depends very materially whether it is viewed with the scales upon it or whether they have been mechanically removed. As seen clinically, usually with a certain quantity of scales adhering to the surface, the patch possesses a whitish-gray color with reddish edges. Denuded entirely of scales it has a florid red or pink color, especially if upon the trunk or upper extremities. Upon the lower limbs, palms and soles, the tint is always several shades darker.

The syphiloderm is less vivid and bright in color and has a lurid, dirty-reddish aspect; it has a dead hue and has been well compared to a section of raw ham. The scales are so few that they do not disguise the color of the true skin.

Character of the scales.—The scales of psoriasis are always produced freely and in great abundance. In syphilis they are formed very slowly and are exceedingly scanty. This point of difference is perhaps one of the most valuable of all the symptoms for diagnostic purposes. It is one about which there is less likelihood of being in error than any other. In psoriasis the scales are loose and non-adherent, the more superficial of which are readily detached from their bed. In syphilis they are thin and adherent, and stick closely to the tissue beneath. The scales of psoriasis possess a silvery whiteness; they have a glistening, nacreous or mother-of-pearl lustre.

The scales of the syphiloderm always have a yellowish, dirty-white look. The scales of psoriasis have the appearance of being new and fresh as if they had been recently formed. In syphilis they have an old, dingy, dried and shrivelled look.

The scales of psoriasis are imbricated, overlapping and fitting over one another like tiles upon a roof. In syphilis they are not imbricated, but are thin, covering the tissue beneath scantily like a transparent membrane.

In psoriasis the scales form rapidly, and in appreciable quantities from day to day. The patient retires at night with the patch thoroughly free of scales and awakes in the morning to find them again present in numbers. The rapidity with which they are ordinarily created is astonishing.

In syphilis they are produced very slowly, through

a period of days or weeks, and even then are but scanty and ill-formed.

If a patch of psoriasis be scraped and denuded of its scales, as for instance by scratching with the nail, the surface beneath will appear bright red in color and somewhat glistening. If the scratching be continued a step farther, the patch readily gives out minute, pin-point-sized jets of blood, springing directly from the apices of the lacerated papillæ of the corium. The derma bleeds very easily. On the other hand, on account of the great deposit of new material, the syphiloderm patch can be rubbed and scratched to a much greater extent without causing bleeding and laceration of the papillæ. In psoriasis the patch is intensely hyperæmic; in syphilis it is only so to a certain extent.

Ulceration.—A cardinal point to be remembered in connection with the history of psoriasis is, that it is never attended by ulceration or moisture of any kind. From the commencement to the end it consists in the production of the same dry, whitish scales, which are continuously cast off in such voluminous quantities. Moisture is never present in any stage of the disease. If the patch have been very much irritated by scratching or external applications, blood in small quantity will appear, but this soon passes off and the old process of scale formation goes on as before.

In syphilis, where there is always a tendency to more than one kind of lesion, a slight degree of ulceration may at times be present. Papules may break down and a loss of tissue be the result, which fact alone would be of sufficient value to determine the diagnosis. Psoriasis leaves no trace of its previous existence except a deposit of pigment in the skin, which in the course of a few months entirely disappears. If no ulceration have been present the syphiloderm leaves likewise only a pigmentation, which, however, is much deeper in color and more persistent in its duration than that of psoriasis.

Effect of treatment.—Psoriasis is often completely relieved for the time being by external treatment, whereas in syphilis local treatment is of little permanent benefit. Psoriasis is influenced decidedly at times by the preparations of iron or arsenic, neither of which exerts any special effect upon syphilis. The syphiloderm is changed and entirely relieved by the preparations of mercury or by the iodide of potassium. In this connection it must not be forgotten that the variety of disease we are considering is perhaps the most obstinate of all the syphilitic manifestations, calling for most judicious treatment. Time is here required to bring about the desired result.

In conclusion I desire again to say that the differences which it has been my aim to set forth as existing between the two diseases, are not infrequently very imperfectly defined; differences which at times it is difficult to describe intelligibly, and which can only be appreciated after a certain amount of clinical experience. Due allowance must therefore be made for the irregularities which are so often encountered in the study of these two conditions.

CURIOSITIES OF COUGH.

Reported to the Medical Library and Journal Association, December 12, 1873.

BY L. ELSBERG, M.D.,

Professor of Laryngoscopy and Diseases of the Throat in the University of New York.

(Continued from page 263.)

IV—MEETING Prof. Weisse in a railway-car one day last summer, he told me of a very curious case of cough he had seen; and on August 11, Dr. Leroy Satterlee placed the patient, young Miss F. H., of Rochester, in my care. She was eleven or twelve years old, obviously precocious in both body and mind, seemingly in excellent health, but extremely nervous. Since the month of May she has had a peculiar affection of the upper air-passages, which consists in a spasmodic paroxysm, every little while, of several wheezing, expiratory efforts. These wheezings have become more frequent in number in each paroxysm, and the paroxysms also occur at shorter intervals. They happen irregularly, but often every few minutes, and now usually eleven or thirteen times in each paroxysm. They are very curious in this, that the expiration of air is broken up into a number of panting or whistling wheezings, which cannot be described in words.

It struck me at once that there was no vocal sound heard in the paroxysms, and that the larynx was therefore probably free from disease. Examination confirmed this: I found the sides of the pharynx swollen, spongy, and flabby, the tonsils and the infra-tonsillar glands enlarged and nodulated, the mucous membrane in the neighborhood of these glands infiltrated and degenerated. On experimentally irritating this membrane by touching it with a sponge dipped into a solution of persulphate of iron, the paroxysms were induced, as I predicted they would be, with greater vehemence and frequency; while on removing portions of the tonsils and of this tumefied mucous membrane, these peculiar paroxysms, that had resisted all internal alterative and antispasmodic treatment for months, ceased.

A further curious feature in this case is the development of chorea. I saw her last on the 20th of August, when she bade me good-by, and was so happy and grateful for her cure that I had to calm the fervor of her expressions. She spoke in a nervously-excited manner of what she had passed through, the various medicines she had taken, and the operations she had undergone. I requested her mother to give her no more medicine, but to keep her very quiet, with proper nourishment, exercise, etc. In the afternoon of the same day (this was Wednesday, and I am now about to quote from her father's letter, dated September 5) "she became intensely nervous and very weak. This grew rapidly upon her, and the next day her limbs and body also twitched and shook as if she were under the influence of a continuous electric shock. On Saturday we brought her home in a very exhausted condition. We waited some days, in obedience to your request that she should have no medicine, and also in the hope that rest and home-nursing would soon bring her around. But her twitching and jumping grew so fearful that we called in Dr. Dean, who at once pronounced the case St. Vitus's dance."

V.—The kind of cough now to be described, although peculiar, is less rare and strange than any of the preceding. It is a harassing, husky, whistling cough, which, once heard, is not easily forgotten. From its sound we may know that it comes from the larynx, and that something, either a me-

chanical obstacle or muscular paralysis, prevents the vocal bands from coming into apposition. Whenever we hear it, especially in connection with a peculiar husky voice, we may make a guess at the alternate diagnosis before laryngoscopical examination.

As characteristic instances, though not as rarities, I may relate the following cases:

F. O., German; æt. 25; unmarried; carpenter; residing nine years in New York; of healthy family, especially as to lung- or throat-disease; always enjoyed good health until two years ago. Since then an exceedingly troublesome cough gradually developed itself, without any cause so far as he knows. Soon after, he noticed that his voice was becoming hoarse. He thinks that the hoarseness came on later than the cough, although he might have overlooked it at first. At all events, at present his voice is quite husky, the cough exceedingly harassing, and the peculiarity of voice and cough above referred to is very well marked. The hoarseness has for some time been exactly as it is now; it does not change; but the cough ordinarily is less severe for several weeks or even months, and then "on taking cold" becomes worse. For over a week it has now been more troublesome than ever it was before. In the intervals of coughing he frequently makes a peculiar and noisy effort to clear the throat, without, however, any expectoration.

The patient has never had venereal disease; his general health is rather poor; he has but little appetite, and is inclined to suffer from indigestion and costiveness. I omit the further details of his condition stated in my note-book, except to say that his lungs are healthy. He complains of no pain in the region of the larynx, but experiences occasionally a fullness, especially in changes of the weather. The laryngoscope showed a small, white, conical excrescence at the posterior wall of the larynx, just inside of the inter-arytenoid fold.

Mrs. L., æt. 36 years; mother of five children; generally enjoyed good health until two or three months ago, when she noticed some difficulty in swallowing liquids, more especially warm soup or cold water. Gradually she became hoarse and affected with a cough, such as I have described. Now the cough is very frequent and troublesome, and hoarseness and dysphagia continue. It is characteristic in this case that she can speak or even sing falsetto notes clearly, but the moment she attempts to use her chest voice the husky squeak comes in. The laryngoscope showed partial paralysis of the vocal bands.

(To be continued.)

ON THE COMMUNICABILITY OF SYPHILIS AFTER IT HAS BEEN APPARENTLY CURED.

BY H. E. WOODBURY, M.D.

WE propose to discuss briefly in this paper the following questions: *First*, Is syphilis a curable disease? *Second*, If so, how shall we determine when the disease is eradicated? *Third*, Can a person who has been apparently cured communicate the disease?

I. Constitutional syphilis results from the introduction of a specific poison into the circulation. It matters not at what point this enters, the result is all the same. There is a period of incubation varying in duration, according to the peculiar con-

dition of the system or the idiosyncrasy of the individual.

During this period the poison is producing its morbid influence upon the blood, which, when completed, manifests itself by certain peculiar and unmistakable indications. In order to answer the first inquiry, we have but to consider whether it be possible in any case to remove a poison from the blood. We all know that many derangements—a large class of diseases—result from this cause,—a blood-poison. Thus, we speak of the fever-poison, the cholera-poison, the poison of yellow fever, etc. The fact that certain types of fever, and the exanthemata which have their origin in a vitiated condition of the blood, as evidenced by the eruption,—an attempt on the part of the system to eliminate the poison through the surface,—are controlled by proper treatment, goes to prove that nature always strives to eject the enemy; and we may greatly assist her in the oftentimes unequal conflict.

Dunglison, in his definition of virus, says, "We speak of the variolic, vaccine, and syphilitic viruses," thus placing these several types under one common head, so far as their action is concerned. Now, as we well know that the variolic poison may be successfully combated, no injurious taint remaining after the patient recovers, and as the vaccine poison wears itself out after a time, as re-vaccination sufficiently proves, may we not naturally enough conclude that the syphilitic will yield to a judicious course of treatment? We would by no means underrate the *vis medicatrix nature*,—an aid the practitioner should never ignore, for nature is our faithful ally in all such cases. But we should undoubtedly aim to assist her in the good work by the administration of such remedies as experience has shown have a tendency to aid in the elimination of the poison. Our own experience and observation, confirmed by that of others whose opportunities for studying this disease have been most favorable, lead us to the firm conviction that syphilis is a curable disease; that it may be so completely eradicated by a thorough course of treatment that, while the syphilitic diathesis may still remain, the subject of it will suffer no inconvenience therefrom, unless he is subjected to unusual exposure, hardship, or privation, or leads a reckless and dissipated life.

II. How shall we determine when the disease is eradicated? This is a question of great importance, for upon its correct solution the health and happiness of others besides the patient may in a high degree depend. A hasty or careless answer should never be given in such a case. So long as any one indication of the disease remains, we may be sure that our patient is not exempt from future trouble. The treatment in these cases must be prolonged for months after every symptom has disappeared, taking care to keep the system of the patient in an above-par condition during the latter part of the course, by the administration of tonics and a generous and nourishing diet.

When such a plan has been persevered in for several months after every indication of the disease has disappeared, we may, I believe, be justified in pronouncing the case cured; but we should care-

fully examine and satisfy ourselves that no symptom of the disease remains before we give such an opinion. Can we err in so doing?

III. Can a person who has undergone a thorough course of treatment, and has been apparently cured, communicate this disease to another? If the statements of the parties in the case we are about to report could be depended upon,—and these statements seemed to be made in good faith,—the affirmative would be proven. The facts and statements we give, vouching only for the facts so far as they came under our immediate observation.

Case.—Mr. —, a widower, aged 40, by occupation a tinner, called on me in the spring of 1870, and desired me to cure a large indurated chancre that was very troublesome to him. I applied acid. nit. to the ulcer, ordered a lotion, and told him that secondary symptoms would undoubtedly follow. In about six weeks headache, sore throat, syphilitic roseola, enlargement of the post-cervical glands, etc., proved my prognosis. He was at once put upon a mercurial course, and in a short time the symptoms yielded. Mercurials and the iodides were taken perseveringly for seven or eight months, when the only symptom that remained was a few mucous patches on the tongue. These were mopped with a solution of argent. nit., and, although somewhat persistent, after a time disappeared. On account of them, the treatment was continued for more than a year longer, making the whole course of treatment a little less than two years. Among the remedies used were hydr. protiodid., hydrarg. chlor. corros., potass. iodid., calcii iodid., Fowler's solution, syr. ferri iodid., and the bitter tonics. For many months before the suspension of treatment, not one trace of the disease was apparent.

Some months after this (in the summer of 1872), the man called to ask me if I thought it safe for him to marry. I examined him, and, finding no indications of the disease remaining, save the cicatrix of the chancre, expressed myself affirmatively. Soon after, he was married. And now comes the peculiar feature of the case. About two months after his marriage he wished me to call and see his wife, who was suffering from a painful sore on the genitalia, and who had, as he expressed it, "very suspicious symptoms." I did so. An examination satisfied me at once as to the nature of the case, but I hesitated to give a decided opinion. Three other physicians saw the case. One of these entertained the same opinion that I did; the others were not quite sure, and reserved their opinion, probably from prudential motives. The woman declared that she was, and ever had been, a chaste woman, and that the disease was contracted from her husband. On the other hand, the husband stated that he had not exposed himself since he contracted the disease, two and a half years before,—not after he was apparently well. An examination of the husband was made at the time his wife was affected, and no indications of the disease could be found, although he had cohabited with her regularly from the date of his marriage up to that time.

About four months later, the husband presented himself with a characteristic syphilitic ulcer on his leg, about as large as a half-dime. He had no other symptom, and had not suffered from a fresh or recent chancre.

This case would be instructive and valuable if the statements of the parties could be verified. It would prove that no course of treatment, however thorough, affords perfect immunity from this disease in the future. Bumstead (p. 523) says, "Those who have enjoyed the greatest facilities for observ-

ing the effects of treatment are nearly unanimous in the opinion that absolute security can never be attained." But in cases where treatment long continued fails to cure, should we not expect to find some indications of a relapse, ere the disease could be communicated? Can a poison so latent as in this case, where no indications of its presence remained, possess infecting properties? If so, we have yet some things to learn as regards the pathology of syphilis.

In the report of Columbia Hospital, D. C. (p. 118), may be found the record of a similar case. But the husband had suffered from what he called "rheumatic pains in his bones," and the wife never had a primary sore. Langston Parker gives two instances in which the secondary taint was communicated to the wife by the husband, no primary lesions being present. Now, we freely admit that secondary lesions are communicable, but we cannot believe that a chance would be the result, for in both of Dr. Parker's cases we are informed "the wives had almost precisely the same symptoms that were developed in the husbands."

We have brought this subject before the profession in the hope that if any one has met with such a case (both of the parties being reliable) he would give it publicity. We can only add that in this case *some deception must have been practised or some mistake made*, as we verily believe. Speaking of it to a medical friend in New York,—a gentleman of experience and research in such matters,—he informed us that he had met with such cases, but always succeeded in clearing up the seeming mystery in which they were involved, before his treatment terminated. It is unfortunate for us, owing to the nature of the disease and the culpability or even criminality that may attach to it, that all the statements of parties implicated must be taken *cum grano salis*, for otherwise we should have but little difficulty in arriving at a true knowledge of the phenomena that characterize in all of its gradations that persistent and loathsome disease, constitutional syphilis.

WASHINGTON, D. C., Nov. 10, 1873.

A CASE OF DROPSY OF THE LEFT PLEURA CURED BY THE USE OF LAXATIVES AND DIGITALIS.

BY C. P. ALLEN, M.D.

ON the 15th of September last I was called to the village of Ulster, a distance of eight miles, to see a little girl. From her mother I learned the following history of the case:

The patient was six years of age, and had always been a fleshy, healthy child until the last six weeks; during which she has been losing flesh and drooping without complaining of pain, but her breath was very short, especially after even slight exertion. She was also unable to lie on her right side, because she could not breathe. The day previous to my visit, while at a dressmaker's, it was observed that the left side was larger than the right. This discovery, in connection with the shortness of breath and decline, induced her parents to call me to see her.

On examining the patient, I observed the left side had a rounded form, the intercostal spaces bulged, and there was very little motion of the chest in respiration. The left side measured three-fourths of an inch more than the right side. The heart was seen and heard beating to the right of the sternum. The whole of the left side was dull on percussion from base to apex. No respiratory sound was audible over any portion of the side, and dulness was observed beyond the median line.

On the right side the resonance was normal, and there was puerile respiration. Pulse 130, respiration 36. The child had evidently lost considerable flesh, but was not greatly emaciated; yet her countenance wore a tired and anxious aspect. Her step was slow and measured, bowels slightly constipated, skin dry, urine high-colored and a little below the natural quantity.

Here we had evidently to deal with a very copious effusion of liquid in the left pleura, that had stolen upon the patient without any known cause. I considered this a proper case in which to use the aspirator for the removal of the fluid, but, having no instrument for that purpose with me, and being several miles from home, and the symptoms not demanding immediate relief, I determined to give her laxatives and diuretics a few days and observe the effect. Two grains of hydrargyrum cum creta were prescribed to be taken three times a day, and it was ordered that the left side should be kept constantly enveloped with flannel wrung out of hot water.

On the 17th I visited her again, and found the bowels had moved several times, and were still rather loose. Other symptoms about the same as when seen last. Prescribed four drops of tincture of digitalis every six hours, and continued the use of hydrargyrum cum creta at night when the bowels were not sufficiently free; fomentations as before.

26th.—I visited the patient again, with the expectation of drawing off the fluid by aspiration, but, on examining her, found that she had had rather a copious action of the kidneys, and that her respiration was reduced to 26, and her pulse to 115. The heart was heard under the sternum, and respiration was audible, though not natural, at the apex of the lung.

Treatment continued as before. Two weeks later I found the respiration nearly normal, pulse 80; the heart had assumed its natural position, but a little dulness was heard at the lower part of the pleura. Respiratory murmur not quite free. The lung was evidently still suffering to some extent from compression, but was rapidly regaining its normal function. Her appetite was good, and she could lie on either side without dyspnoea. The continuance of the digitalis was advised, morning and evening.

I have not seen the patient since, but was informed by an aunt of the little girl to-day, December 15, 1873, that she had become quite well, and was as strong and healthy as before her sickness.

The above case is interesting in at least two things. First, the insidious manner in which the disease made its appearance, and the amount of effusion without pain; second, the ready manner in which it yielded to gentle laxatives and digitalis.

I am well aware that serous membranes pour out serum very readily, but in most instances where there is irritation or slight inflammation sufficient to produce effusion in the pleura, more or less acute pain is felt in the side.

I have always found it difficult to remove effusions in closed cavities and cysts by means of laxatives and diuretics, or at best the process is a very slow one.

In a case of large effusion in the pleura, it is very

readily understood why it is so. The lung is greatly compressed by the fluid, so that little or no air enters it, and the blood-vessels are in a congested condition. The sound lung is more or less congested and compressed by the over-distention of the opposite pleura, and it is well known that this condition is unfavorable to absorption. Another reason is that coagulable lymph is very apt to coat over the pleura and thus render absorption slow and difficult.

In the above case, the probability is that very little lymph had been effused, the inflammation having been so mild in its character, and that the laxatives given relieved the bowels and portal system by a direct action, and the blood-vessels of the chest by a secondary action, thus favoring the effect of the digitalis as a diuretic and the accompanying relief of the effusion.

We have often found very marked relief from the use of digitalis in anasarca of the legs with or without effusion in the peritoneal cavity, occurring in elderly people having a quick and feeble pulse, with atony or enlargement, and dilatation, of the heart.

ATHENS, Penna.

ELECTRICITY IN THE TREATMENT OF CHILBLAIN.

BY ALONZO L. LEACH, M.D.

PERHAPS no disease so simple in its origin and pathology is so difficult at times to cure as chilblain. At this season of the year every physician's office presents its cases. It has seemed to me that the various plans of treatment recommended by different authors are but temporary in their results. I have found ordinarily the liq. iod. comp., and aq. ammon., in equal parts, as recommended by Dr. Balfour, of the Royal Military Asylum at Chelsea, the most marked in its action.

Last winter, while treating a number of cases, it occurred to me to try the influence of electricity. I accordingly applied the secondary or induced current, and the result fulfilled my anticipations. This winter an aggravated case, of long standing, in a gentleman of this city, presented itself to me, and I pursued this mode of treatment: the relief afforded was so decided as to leave no room for doubt in my own mind of its efficacy.

We have, as the ultimate result of frost-bite, a partial or complete paralysis of the vessels, as well as a nervous element, evinced by the pain and intolerable itching. Electricity tends to give tone to the parts and restore them to their normal condition. This is the result sought for in all applications, but they only do so temporarily in a majority of cases. The cause reappearing, the pathological condition still remaining, we have a return of all the symptoms. I am convinced, from the success met with in those cases where I have used it, that electricity, applied for a period of time every day, or at longer intervals, as the case may be, will place the parts in a healthy condition and effect a permanent cure.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

SURGICAL CLINIC OF PROF. JAMES R. WOOD.

Reported by F. W. CHAPIN, M.D.

CASE OF STONE IN THE BLADDER—BILATERAL OPERATION.

J. M., 47; male; Ireland; bricklayer. Patient was wounded in the late war, in 1863, and had paraplegia for some weeks in consequence; has recovered almost entirely. He denies having had venereal disease; has been a hard drinker. Fourteen months before admission he noticed on passing his water that it was tinged with the color of blood. About this time, also, he began to be troubled at times with incontinence of urine. By-and-by he noticed that often when he wished to pass his water he could not, and that, after waiting, it would begin to flow and soon suddenly stop. This sudden stoppage was always accompanied with severe pain at the end of the penis. The desire to urinate became very frequent at last, the patient being forced to make his water every few minutes. At this stage he was admitted to the hospital, December 18, 1873.

On admission, he was a healthy-looking man. He complained of pain in the bladder and perineum; a heavy, dragging sensation in the groin; sharp, lancinating pain extending from the groin to the end of the penis; all increased by riding in the horse-cars or by being jolted in any way. The pain at the end of the penis was always severe towards the end of micturition, and much more so after the act. He occasionally had sudden stoppages of the flow during micturition, as formerly. Severe pain accompanied these stoppages, and during the efforts to void the bladder there was often marked vesical tenesmus. The urine was passed every five or ten minutes, and contained blood, pus, and oxalate of lime.

December 20.—Examination of the urine showed considerable albumen and some pus.

Patient was this day etherized, the perineum shaved, a staff introduced into the bladder, and the stone felt, first by Dr. Crosby and then by Dr. Wood. Being thus sure of the presence of a calculus, Dr. Wood performed his favorite operation, the bilateral, making a curvilinear incision crossing the perineum an inch in front of the anus, and terminating on each side in the ischio-rectal space, midway between the anus and the tuberosity of the ischium. Through this incision the staff was reached just in front of the prostate. The point of Wood's bisector was then held in the groove of the staff, the handles of the staff and bisector approximated, and the bladder entered. A mulberry calculus was removed about half an inch in diameter and of a rough, uneven surface. Very little hemorrhage followed. The patient's testicles were lifted away from the wound by means of a broad strip of adhesive plaster passed under them and around the thighs. His legs were tied together, and he was put to bed. This is the ordinary dressing and immediate after-treatment used in the hospital in uncomplicated operations for stone. At the close of the operation Prof. Wood remarked that he had accomplished two very desirable objects. In the first place, he had removed the stone, the cause of all the distressing symptoms; and in the second place, he had put the patient in a way to get well of his cystitis, for he had removed the cause of it, and had put the inflamed organ at rest and freed it from further contact with decomposing urine, by making an opening through which the urine might escape from the bladder as fast as it entered it.

3.30 P.M.—Patient complains of severe pain on passing his water through the perineal wound.

Ordered McMunn's elixir, \mathbb{M}^{x} l.

4 P.M.—Pulse 84; resp. 20; temp. 98°.

December 21, A.M.—Pulse 78; resp. 21; temp. 96½°.

No hemorrhage had occurred since the operation. Immediately afterwards patient passed a small quantity of urine by the urethra. Since then the quantity passed in this way has steadily increased, and he now passes considerable by the urethra.

4 P.M.—Pulse 88; resp. 23; temp. 98½°.

December 22, A.M.—Pulse 84; resp. 24; temp. 99°.

Patient passed the greater part of his urine by the urethra. Wound is looking well.

4 P.M.—Pulse 92; resp. 30; temp. 99°.

December 23, A.M.—Pulse 84; resp. 23; temp. 97°.

Wound suppurating. Granulations somewhat pale.

P.M.—Pulse 80; resp. 20; temp. 97°.

December 24, A.M.—Pulse 84; resp. 24; temp. 97°.

" " P.M. " 90 " 24 " 97½°.

" 25, A.M. " 96 " 23 " 96°.

" " P.M. " 90 " 30 " 97°.

" 26, A.M. " 96 " 23 " 96°.

" " P.M. " 98 " 22 " 98½°.

Patient's bowels have not moved since the operation.

Ordered a stimulating enema.

December 29, P.M.—Patient's pulse, respiration, and temperature have remained about the same as at last note. General condition excellent. Appetite good. Bowels regular. He has had no pain except when urine passed through the wound. To-day he has for the first time passed all his urine through the urethra. He sleeps well.

January 7, 1874.—Since the 29th ult., patient has passed all his urine by the urethra. The wound is fast closing up, and looks healthy. The urine contains some pus and albumen still, but a less amount of each than before the operation. Patient's general condition is all that can be desired.

TRANSLATIONS.

THE GROWTH OF MUSCULAR FIBRE AND OF THE MUSCLES IN THE FROG.

DR. PETROWSKY (*Centralblatt f. die Med. Wissenschaften*) proposed to himself two questions to be solved by his investigation:

1. What histological changes in the muscular fibre took place while the frog grew from the tadpole condition to a length of eighty mm.; and 2, whether in this period of time any new growth of muscular fibres occurred.

His observations were made upon muscular tissue, the fibres having been treated partly by diluted acetic acid and glycerin, and partly by acetic acid alone, and then teased out. Transverse sections were made of dried muscle, and treated with the same fluids. He found that at the termination of the tadpole period the muscles consisted of spindle-shaped fibres with oblique striations on the periphery, while in their middle was found a row of large oval nuclei. They possessed as yet no sarcolemma, and were closely surrounded by spindle-shaped nucleated cells. Among these fibres are found some which have nuclei also on the surface, and which are not entirely covered by the obliquely striated matter, but are only thrust into it, while on the periphery they are lost in a thin boundary-line which forms the commencement of the sarcolemma. These nuclei are at some distance asunder, so that but one or two are visible in one field of the microscope. In very small frogs having a length of but ten mm. the fibres named above are in excess, but the peripheral nuclei are more numerous, and groups of two or three nuclei

are found lying in a line parallel to the axis of the fibre. When these fibres are torn, the existence of a sarcolemma can be demonstrated. The peripheral nuclei are attached to the sarcolemma, and are partly oval, but for the most part appear as sharply-defined bodies, like little bars, with their long axes parallel to the axis of the fibre. They are also found free in the field of the microscope. This same form can also be found among the nuclei of the row at the axis of the fibre after the addition of concentrated acetic acid. This change is especially distinct in the muscular fibres of the house-fly and in those of the head of the frog. By adding concentrated acetic acid to a preparation of muscular fibre prepared by teasing upon a microscopic slide, the change from the oval form could be seen in progress. This second form is simply the first or oval nucleus seen in profile.

The length of time during which the fibres remain in this condition varied in different frogs which were the subjects of examination. When the frog had grown to a length of thirty mm., still further changes took place. The axial row of nuclei vanished, as well as most of those on the periphery of the fibres, and in their places appeared rows upon the periphery which were arranged parallel to the axis of the fibres.

By a transverse section they were found lying under the sarcolemma, although but few of them seemed to have any connection with that membrane.

No observations were made which appeared to justify the assumption that the rows of nuclei found upon the surface of the fibres had their origin in those previously observed in their axes.

In addition to these changes, in some cases it appears that a growth of the muscles caused by a new growth of fibres takes place. In making an examination of the entire gastrocnemius muscle, all the forms described above were found, from the earliest up to those characteristic of the muscles of the full-grown frog; but no evidences were found of growth due to splitting of already developed fibres.

From his observations, Dr. Petrowsky drew the following four conclusions in regard to the growth of muscle in the frog:

1. In the tadpole period, the muscle consists of spindle-formed fibres with a row of oval nuclei in the centre. There are no sarcolemmæ or peripheral nuclei existing.

2. On the periphery of most of the muscular fibres, when the frog has attained the length of ten mm., sarcolemmæ and nuclei make their appearance. These nuclei look like little bars, but are really oval seen in profile.

3. The central row vanishes, and most of the peripheral nuclei free themselves from the sarcolemma, increase in number by division, and arrange themselves upon the surface in rows parallel to the axis of the fibre. The increase in size of the muscular fibres is proportional to the increase in number of these peripheral rows.

4. The formation of new fibres assists in the growth of the muscles, but this new formation is not due to division of pre-existing fibres.

WILLIAM ASHBRIDGE, M.D.

DISCHARGE OF ASCARIDES FROM THE URETHRA.—Prof. Dujardin reports the passage of three ascarides from the urethra of a man 72 years old. The passage of these parasites occupied ten days, and occasioned the patient much suffering. The specimens are preserved in the anatomical museum at Genoa.—*Boston Medical and Surgical Journal*; from *La Nuova Liguria Medica*, No. 18, 1873.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 7, 1874.

EDITORIAL.

SOME OF THE USES OF HOSPITALS.

A GOOD deal has been said, and with more or less reason, as to the direct relations of hospitals to the community in this city, and especially as to the mode of their management and the grave defects under which some of them labor. We, as doctors, have felt keenly, and, where men dared to do it, have plainly pointed out, the errors into which the managing boards of laymen fall.

Perhaps a hundred physicians and surgeons in this city devote their many hours of unpaid work to the care of the sick in our hospitals, and yet scarcely once in years is there an example of neglect or want of care. Nay, more,—no sick people in any land are treated with more courtesy or steady kindness than that which marks the bearing of hospital physicians in this city to their suffering fellow-beings. We say this the more freely because a manly and tender consideration for the sex and the feelings of hospital patients is often wanting in France and Germany; and we say it, too, the more freely, since we are about to call the profession to account for defects which do not exist in Europe. What direct value to the community hospital-wards possess, is plain enough. What indirect value they should have will depend upon the tendencies, training, organization, and capacity of their staffs, and upon what demands the general medical conscience makes upon them. In plainer language, the progress of medicine rests largely on the use which men make of hospitals, since very little valuable

study of disease can be done in private practice. So true is this that, as every one knows, the history of Guy's, La Charité, Hôtel-Dieu, and other great hospitals, is the history of modern medical discovery.

The hospital surgeon has, in the first place, direct daily duties to his patients, but he has also a possibly higher duty for which he is presently responsible to the profession. And this duty arises out of the fact just stated,—that the clinical experience of private practice is usually valueless as a means of research. To the hospital physician and surgeon fall, therefore, certain chances of study which are not within the grasp of others; and so far as he fails to use them, does he also fall short of the unwritten duties of his post. No manager or fellow-doctor may call him to task; but, when years have gone by, and his miles of walks through his wards have brought no more than a mere selfish growth in personal experience, the profession at large may with reason urge that his stewardship of opportunities has been in fact a failure. We shall at once be asked by the anticipative reader what we mean, what kind of work we have in mind, how it is to be done; and perhaps, too, if he be critical and reads the journals, poor fellow, what kind of medical experience should not be given to their crowded pages. To us, answering, it seems that first of all, and easiest, we should be constantly getting from our staffs clear, well-studied, sharply-told experiences of their trials of novelties, whether they be of foreign growth, or among the host of new remedies, good or bad; but surely some most potent, which the so-called eclectic employs, and of which we know but little.

We might, for example, ask for a careful report, kept up for years, in brief tabular form, of all the cases in which anæsthetics are used in our hospitals; and not merely as to their fatal results, but of the relative frequency of those half-deaths and close rescues from danger which we have all seen, and shuddered to see. Next in ease of study come such as the thermal and other symptoms of diseases essentially of home-growth, like our malarial fevers, sunstroke, and our common summer-complaints.

Without entering into details, it were easy to call attention to many lines of clinical investigation which would be, to some extent, novel, either because they would deal with diseases which are more common here than in Europe, or because we should soon find that even well-known maladies not due to specific poisons put on, with us, peculiarities bearing some relations to our highly-marked seasons, and well worthy of study. Of course, such researches are difficult, and require trained clinicians; but

there are men enough among us who are competent, and who should be called upon to justify, by work of this nature, their right to the posts they hold. We have yet to learn that managers ever concerned themselves with this question; but they may feel quite sure that the men of this turn who find not one, but many, interests in their wards, are of all men the best, and the most likely to overlook no minor duties.

We are, of course, well aware that a few hospital physicians study their cases with care, and keep good notes; but, for various causes, the work so done comes to little, owing chiefly to a too great tendency to study each case in a disconnected way; or, haply, to a lack of training, or of interest, or of defined and accurate purpose. Abroad, we find hospital physicians carefully accumulating material year after year, bearing on some one disease, and at last drawing it anew with some novel light upon it, or refreshed, as it were, from the older pictures, by the aid of modern methods. Where now do we see such papers from our own great hospitals? And what is it that hospitals give us in the place of such work? Isolated cases,—Dr. A's case of this or that, reported by Dr. B; cases with or without post-mortem sections; cases which are either every-day commonplaces of diseases, or else are purely curiosities, but which, in any event, have no true value; cases which, grave or petty, should have been filed away until the commonplaces, by their number, would grow into value, or until the rarities, by like additions, should so multiply as to enable a shrewd observer to teach from them some useful lesson. But worse still are those wearisome reports of clinics, which, as a rule, are quite wanting in all of the higher qualities that justify, and but rarely justify, the publication of a class-teaching. Now and then we light on one of them which is an honest, thorough going-over of a subject with the last modern lights on it, and a certain freshness of treatment which makes the absence of novelty in facts or commentary endurable. Such lectures are at least what the lay-journalists call "good padding," and are, no doubt, heard with pleasure by students, and read—if read at all—without disgust. But, to say the best of them, as concerns the space they occupy in the journal, they are what Mr. S. Weller called "werry fillin' at the price."

There are other clinical reports which are of the lazy type. Dr. P reports the clinic of Prof. Q, the latter permitting or requesting the service. Then it is, indeed, that we get the worth of our time and money. A valuable ten lines on angina,—well enough if students alone were the looked-for read-

ers,—operation for hare-lip, etc., a case of Potts' disease, with no end of commonplaces or of statements which one reads more in sorrow than in anger, and which one would read more in mirth than in either were it not for the consequences of such teachings; or we have a case of hemiplegia, which proves to have been just the ordinary typical example; or, haply, Dr. Could reports Dr. Would: his case of local chorea,—which, as it sounds attractive, we read, to find at the end, like Sir Charles Coldstream, that "there is nothing in it." Now, all this sort of thing is well enough in a small Western town, which will have its medical journal; but it is provincial in tone, and is fatally indicative of a too eager desire to be advertised to the profession, and of a thorough lack of the mood of patient, watchful labor, which is only eager for truth, and which too much values its own time to waste that of another. The number of medical text-books produced by the profession may be pointed to as an evidence of useful activity in the medical mind of Philadelphia; but, valuable and necessary as these may be, to have much weight they must be the offspring of minds which have really added something to the science of the day; since, otherwise, they will be lacking in individuality, and will be simply and purely compilations more or less cleverly framed. In other and plainer terms, the prestige of a city which claims to be called, and which once was, a great medical centre, must always depend upon the amount of original work which it evolves; and it is just this which everywhere in America has been sadly wanting. In Boston there is almost none; in New York very little, despite immense clinical material; and with us, although more has been done than in either of the two places named, the amount and character of what we have to show in this direction are put to shame by many a little town in Europe.

We have pointed out that some of the blame of this state of things lies with the holders of hospital posts, with their lack of interest, of training, and of conscientious comprehension of their duties as hospital attendants. But a part of the trouble resides also in our absurd methods of hospital organization,—a subject with which we propose to deal at another time.

IT will be remembered that the Baltimore medical experts in the Wharton trials affirmed subsequently that they had been forced to do what they did by process of law; also that Mr. Thomas in his pamphlet stated that this was not true,—that their action was voluntary, beyond all law, that they were

practically the prosecutors, and that on this ground compensation had been refused them. As corroborative of this, we clip the following from the *Evening Bulletin* of this city,—issue January 24, 1874. We give it exactly as it appeared:

"FEE-BILLS OF THE 'FORCED' EXPERT-WITNESSES.—In the Baltimore City Council proceedings, at their last meeting, we find the following:

'Mr. Heusler presented the petition of Dr. S. C. Chew for pay for services in the case of Mrs. Wharton—attendance as medical expert twenty days, at \$20 a day, on first trial, and sixteen days at second trial, at \$20 a day; and for exhumation and examination of the body of General Ketchum, \$50. Also, the petition of Dr. P. C. Williams for pay for thirty-three days' attendance on first trial, at \$20 a day, and sixteen days at second trial at \$20 a day, and \$50 for exhuming and examining the body of General Ketchum. Also, petition of Dr. F. F. Miles, for pay for eight days' attendance at the second trial, at \$20 a day, and \$50 for going to Washington. The entire amount of Dr. Chew's bill is \$720, of Dr. Williams's \$1030, and of Dr. Miles's \$210. Referred to Committee on Claims.'"

REVIEWS AND BOOK NOTICES.

PARKES'S MANUAL OF PRACTICAL HYGIENE. Fourth Edition. Philadelphia, Lindsay & Blakiston, 1873.

This handsome octavo of six hundred and seventy pages is undoubtedly the most elaborate hygienic treatise in the English language. Full of facts and abounding in figures, sometimes even entering into abstruse calculations in mathematics and physics, its style is still uniformly clear and agreeable. Whatever labor its study presents belongs to the matter, not the manner, of its presentation. Yet we can hardly call it a well-arranged book. The classification of subjects is in itself a reasonable one; but in dealing with them the same topics come up again and again, with many iterations of the same statements. While this must add a few pages to the bulk of the volume, its excuse is, we suppose, that it may promote the familiarity of the student with important facts.

Dr. Parkes has evidently written his book with the interest of the soldier and that of the medical officer of the army always in view. The last one hundred and eighty pages (nearly one-third of the book) are occupied with the "service of the soldier" in its special sanitary relations at home and in foreign countries. A number of matters are also discussed in the other portions of the volume, in a manner not equally requisite for all readers. Still, the facts and laws of sanitary science are so general that the student of hygiene may find, with proper search for it, information upon nearly all the subjects belonging to a non-military work.

With the fourth edition before us, it is not needful to analyze all the contents of a book already so widely known. A few topics of importance may be referred to, with the purpose of bringing out Professor Parkes's "last word" upon them.

The learned author is by no means only an accumulator of other men's observations. He is an original and skilful experimenter of the first scientific rank; and also familiar, personally, with the experience of the physician. Yet novelty of opinion does not charac-

terize his book. Dr. Parkes inclines, it seems to us much more than is necessary, to respect, and even to yield to, the "current (especially British) opinion." On the whole, we have felt a certain degree of disappointment in concluding that we are to look to him, as a teacher, rather for the able presentation of those views upon sanitary subjects which prevail, than for the advancement of sanitary science on the basis of new facts and independent thought. From this it follows that, where doubt and controversy cloud a subject, this murkiness is somewhat reflected upon his pages; his candor and judgment forbidding the concealment of facts, even when their clear interpretation would annul the accepted professional dogma of the hour.

We find this approach to confusion upon several topics. One of these is that of the causation (as bearing upon the prevention) of typhoid fever. Following the lead of Canstatt and Budd, Dr. Parkes remarks, in one place, concerning the propagation of typhoid by impure water, "I think we may now safely believe that the presence of typhoid emanations in the water is necessary." On another page, nevertheless, we are told, "There are, however, some difficulties." These are the occurrence of typhoid fever, in well-marked instances, in the presence of sewer-air without any possible evidence of the vicinity of a person with the disease; and yet more, its breaking out in those who "have not been exposed apparently to sewer-air, or fecal emanations, or to the charge of any typhoid contagion." With seeming disinclination, he barely alludes to the possible supposition "of an origin apart altogether either from fecal emanations or a prior case of the disease." "Other modes of origin and transmission are not disproved." We like much better the *positive* statement of Dr. A. Flint:* "Although it may be undoubtedly communicated in some way from the sick to the well, under ordinary circumstances it is not diffused by contagion;" "facts appear to show conclusively the spontaneous generation of the causative agent in the great majority of cases."

Upon cholera, Professor Parkes's pages are saturated with the now current theory of the "portability" of the cause of the disease. Dr. Macnamara is cited as even fixing the period of danger in choleraic drinking-water. In that which has been contaminated by the discharges of cholera-patients, *vibrio*es appear with great rapidity; when this vibrional stage is replaced by the *ciliated infusoria*, the water (according to Macnamara) is no longer dangerous.

Facts contrary to this theory do not weigh much with Dr. Parkes; "the portability being certain." The idea of migration without human transportation is not entertained; notwithstanding the numerous facts (quoted in this work as well as elsewhere) showing the very frequent non-production of cholera by exposure to choleraic excrements; and, further, notwithstanding the fact that Pettenkofer could find no "evidence whatever" of this mode of transmission at Munich, nor Günther in Saxony, nor Volz and Witlacil in Baden or near Vienna; and that cholera moves across the sea, lighting in mid-ocean upon vessels which had left healthy ports; besides those obvious relations (proverbially present in India) of the disease to *season* and *locality*, which might not unreasonably have always forbidden the exclusive ascription of the extension of cholera to stercoraceous imbibition from becoming the "prevailing opinion."

Our author, when he extends the same or a similar theory to *yellow fever*, declaring (page 480) that "the discharges, especially from the stomach, probably spread the disease," certainly appears to us to run it into the ground. With that descent, however, the pro-

* Practice of Medicine, fourth edition, p. 883.

gress of this hypothesis is not quite ended; for the "grundwasser" of Pettenkofer, and the "intergrundwasser" of Virchow, next take it up. Reaching the surface, *current opinion* makes of it, in the air, *contagion*, in the form of excremental dust; while Hallier leads a few followers (especially *not* the botanists) to find in it swarming sporoids of the micrococcus of *urocystis oryzae*.

Especially noticeable it is, in view of the positiveness with which the above-mentioned theory is advocated by Dr. Parkes, how candidly and repeatedly he states the failure of those measures of prevention which it dictates. "The results of disinfection of the discharges have not hitherto been encouraging." "The evidence of the use of the plan in the last European epidemic is very disappointing." Yet every one knows that the effects of sound, thorough, general *sanitary improvements*, not tied to any theory, have in the last times of prevalence of cholera in many populous communities been most satisfactory in lessening much the mortality from the disease. Dr. Parkes's estimate of quarantine against cholera must be here added: "An island, or an inland village, far removed from commerce, and capable for a time of doing without it, may practise quarantine and preserve itself; but in other circumstances, both theory and actual experience show that quarantine fails."

The theory of *disease-germs* is treated by Professor Parkes with equal justice to all authentically-recorded facts and candid indecision in regard to conclusions. Lister, Beale, Hallier, Klebs, Tyndall, Burdon Sander-son, Bastian, Lex, Woodward, Wood, and Lewis are all cited. "That these creatures," he says, "are concerned in many diseases is clear." Yet "the present view is that while it has not been conclusively shown that bacteria or vibrios are in themselves hurtful (though they are held so by some observers), their presence indicates the co-existence of certain organic substances and putrefaction; and putrefactive substances in water are certainly dangerous." "Disinfection must rest at present on its own experimental evidence." Dr. Parkes affirms, upon his own observation, that while carbolic acid rapidly arrests the growth of fungi, it will not completely destroy them; "the carbolic acid withers without actually killing the fungi" (p. 131).

On the now much-debated question of *sewage-removal and utilization*, Dr. Parkes writes with excellent judgment, concluding that no one method as yet devised is equally applicable to all localities and circumstances. Water-sewerage, irrigation, precipitation, filtration, and the earth-system may all find their proper places, in different communities; while no final, perfect solution of the problem, at once sanitary and economical, has yet been attained.

One of the most instructive portions of this book is that upon the use of alcoholic beverages. Here Dr. Parkes has been an original observer, and has contributed facts of cardinal importance. Yet his deductions are restrained from advancing so much as (it appears to us) those facts would warrant beyond the views commonly accepted, now, it is true, with diminishing confidence, in Great Britain. He scarcely contravenes, as we believe he might have done with great advantage, Dr. Anstie's opinion, that one ounce of alcohol daily is a wholesome, if not required, portion for an average adult man in health.

But we must with reluctance cut short, for want of space, our imperfect account of this very valuable treatise. We may conclude with some of Dr. Parkes's own words: "Were the laws of health and of physiology better understood, how great would be the effect! Let us hope that matters of such great moment may not always be considered of less importance than the languages of extinct nations, or the unimportant facts of a dead history."

H. H.

ON THE STRUCTURE OF CANCEROUS TUMORS, AND THE MODE IN WHICH ADJACENT PARTS ARE INVADDED. The first of the Toner Lectures, instituted to encourage the Discovery of New Truths for the Advancement of Medicine. Delivered by J. J. WOODWARD, Assistant-Surgeon U.S.A.

Just now it is *the mode* with some Continental pathologists to attribute many of the ills that flesh is heir to to the baneful influences of the migratory white blood-corpuscle. With these theorists it no longer suffices that the innocent function of supplying red disks be ascribed to the white corpuscles, but they must needs make them serve, when escaped from the blood-vessels and becoming migratory or wandering-cells, as the fertile sources of pus-corpuscles, epithelial cells, etc. Ay, they have even so far distorted these delicate lumps of protoplasm as to fabricate them into the huge monsters of the so-called cancer-cells.

It is needless to state that the prevalence of this hobby of Cohnheimism has extended to Washington, where, to say the least, it seems to have proved thoroughly infectious. Virchow, with his famous doctrine of *omnes cellula e cellula*, is thrown overboard, it being antiquated to imagine any longer that cancer originates by the multiplication of the connective-tissue corpuscles. Thiersch's and Waldeyer's theories of the genesis of cancer-cells by a proliferation from the softer epithelial layers of the rete Malpighi and of the glandular appendages of the skin or mucous membranes, are not adopted by the lecturer. The view of Koester, that cancers of the skin originate in and from the lymphatic spaces and vessels, is only accepted in so far that the brood of small cell-infiltrations, usually observed in the stroma of the marginal portions of cancerous tumors, is placed within the lymph-spaces. These small cells, eventually transformed into the larger epithelial-like cells, are not derived from the endothelium of the lymphatics, as Koester would lead us to suppose, but from the white corpuscles escaped from the blood-vessels.

The swarm of small cells about the terminal buds of the cancer-cylinders, which Dr. Woodward regards as migratory corpuscles accumulated within the lymph-spaces, as well as the presence of "numerous unmistakable wandering corpuscles among the epithelial cells seen in almost all sections of epithelial cancer," have led him to consider the wandering-cell as the most probable source of cancer. These wandering-cells are next made to increase in size and number, at the expense of the surrounding adipose tissue, until they attain the lordly proportions of the epithelial-like cells.

No doubt this new theory of the genesis of cancer was rendered extremely plausible to the lecturer's audience by the exhibition of his clever photo-micrographs; but to us, unfortunately, the printed evidence does not appear quite so conclusive. In fact, we doubt very much, unless more ample proof be furnished, whether much credence will be given to this view of the origin of cancer.

There is no knowing what wondrous things these followers of Cohnheim might yet have led us to accept as growing out of the wandering-cells: if cancer, then why not also round-celled sarcoma, myxoma, glioma, and so on? Fortunately, this uncontrolled enthusiasm concerning the migratory white blood-corpuscle and its functions received an effectual quietus by the experiments of W. F. Norris and Stricker; who showed conclusively that even the fixed stellate connective-tissue corpuscles, when irritated and inflamed, are capable of undergoing a variety of changes both in form and position,—in other words, capable of becoming wandering-cells.

Agreeing with the lecturer that the doctrine of a cancerous dyscrasia of the humoral pathologists is no

longer tenable, we must confess our inability to understand clearly how this theory of his is not virtually a migratory step back to these exploded doctrines. The reader will find this brochure a very excellent summary of the various views entertained by the pathologists of the present time. Its perusal will familiarize him with many authorities as yet inaccessible to the English reader.

R. M. B.

GLEANINGS FROM OUR EXCHANGES.

A RARE PHYSIOLOGICAL EXPERIMENT (*British Medical Journal*, December 20, 1873).—Dr. Brandt, Professor of Surgery in Klausenburg, has placed on record, in the *Wiener Medicinische Wochenschrift*, a case in which removal of the sound kidney took place in the human subject. A healthy man, æt. 25, was stabbed with a bread-knife in the left hypochondrium. Hemorrhage to the amount of three or four ounces followed; and, about three hours after the accident, a fleshy-looking tumor was expelled through the wound by a fit of coughing attended with severe pain. It was replaced by a by-stander, but was soon again driven out by the cough. On his admission into hospital, twenty-four hours after the injury, Dr. Brandt, after a careful examination of the protrusion (of which a careful description is given), arrived at the conclusion that it was the left kidney. Its surface, with the ureter, was torn in some parts, and allowed the escape of a fluid, at first yellowish and transparent, but afterwards sometimes reddish and sometimes turbid yellow. It had an alkaline reaction, a specific gravity of 1.042 to 1.052, contained a large quantity of albumen and mucin, with some hæmoglobin, traces of urea, and an abundance of alkalies and alkaline earths. It gave a sediment, which on microscopic examination was found to consist of pus and blood-corpuscles, masses of nuclei, mucus-fibrils, and fibrinous clots; also epithelium of the kind belonging to the calyces and pelvis of the kidneys. Dr. Brandt arrived at the conclusion that the organ was rendered useless, that its retention endangered life, and that it would be best to remove it. The previous history of the patient did not contra-indicate this: he had had no severe illness, and, though the urine in the bladder contained some albumen, this might be derived from the injured organ. Accordingly, on the fourth day of the injury,—photograph of the patient having been first taken,—Dr. Brandt tied the pedicle of the tumor in two parts, by means of a ligature passed through the middle, and cut it away with a knife. This operation was done on June 7, and on the 23d the patient left the hospital convalescent. No symptoms of uræmia or of peritonitis occurred during the progress of the case. The amount of urine excreted was measured daily up to the 22d. The quantities were the following: June 7th (half-day), 310 grammes; 8th (whole day), 923 grammes; 9th, 905; 10th, 1425; 11th, 1211; 12th, 992; 13th, 1278; 14th, 1222; 15th, 1348; 16th, 1306; 17th, 1296; 18th, 1324; 19th, 1312; 20th, 1437; 21st, 1498; 22d, 1513 grammes. The urine was throughout acid, of specific gravity 1.010 to 1.040, and of normal composition: at first it was of a reddish-yellow color, but afterwards became clear yellow. Dr. Brandt has seen the man several times since the operation. He has no signs of disease of the heart, but complains of a sense of oppression and fatigue, especially in going upstairs, and says that he cannot work as well as before. Dr. Brandt, however, suspects that he may say this to avoid military service.

SLEEPLESSNESS (*The British Medical Journal*, December 27, 1873).—Dr. Dyce Duckworth directs atten-

tion to some causes of insomnia, which, he thinks, are hardly sufficiently recognized or adequately met by the resources of practical medicine. Recent researches have clearly shown that the brain is comparatively anæmic during sleep, and that the blood thus removed from the head is more freely supplied to the viscera and integuments.

The most constant cause, and certainly the most frequent accompaniment, of sleeplessness, is an opposite condition, or one of active and increased cerebral circulation. A species of nocturnal dyspepsia, mild in its character, and producing no actual suffering, may sometimes give rise to persistent insomnia. There may be no symptoms beyond dryness of the mouth, burning of the soles of the feet, and heat and throbbing in the head, and these are probably due to a too acid condition of the contents of the stomach and upper part of the small intestines, caused generally by excess in fatty and highly-seasoned food, in fruit, and in various wines.

Sleeplessness may be due to bodily and mental over-exhaustion, which results in an increased flow of blood to the brain, consequent upon vaso-motor paresis. Again, it may be the result of mere habit, as in those cases where there has been a long course of broken rest; it may be caused by persistent odors, by certain effluvia, by the absence of moisture in the air of the sleeping-apartment, or by an improper elevation or depression of the head.

The treatment in most of these cases should of course be directed to the removal of the cause; but, when it is found necessary to give drugs, bromide of potassium and chloral hydrate are probably the best, both having been shown to diminish the amount of blood circulating through the brain.

RETENTION OF URINE CAUSED BY A FIBROID GROWTH (*The Lancet*, December 27, 1873).—Mr. Henry Smith reports the case of a child, nineteen months old, who, when first seen, was suffering from retention of urine, having passed no water for two days. A very tight phimosis which existed was relieved by division of the prepuce, but repeated attempts at catheterization, both with and without chloroform, resulted only in failure. The rectum appeared preternaturally dilated, and there was a perceptible hardness between it and the bladder. This was thought to be possibly due to blood effused from previous attempts at catheterism or to a calculus lodged in the neck of the bladder. The urine was withdrawn by means of an aspirator, and the operation was twice afterwards performed, but the child gradually sank, and died at the end of four days. At the post-mortem examination a large, irregular fibrous growth was found interposed between the rectum and the bladder, springing apparently from the periosteum of the pubes and ischium, extending under the arch of the former backwards and forwards, and thrusting the urethra out of its course against the left ischium. The microscopic appearances were those of a fibroid or recurrent growth.

FORMULA FOR UNGUENTUM ALTHÆÆ, OR MARSH-MALLOW OINTMENT.—R Lard, 1 pound; curcuma, 2 drachms; water, 4 drachms; yellow wax, burgundy pitch, of each, 6 drachms. Boil the lard, curcuma, and water together, until all the moisture has disappeared; then add the wax and pitch, strain while hot, and stir while cooling.—*Prussian Pharmacopœia*.

REMEDY FOR CHRONIC HOARSENESS.—In chronic hoarseness arising from thickening of the vocal cords and adjacent membrane, the ammoniated tincture of guaiacum is often a very efficacious remedy. It may be appropriately mixed with equal parts of the syrup of senega, and a teaspoonful of the mixture given two or three times a day.—*American Practitioner*.

ETIOLOGY OF PULMONARY PHTHISIS.—In *Archiv für Experim. Path.*, Heft 3, 1873, Dr. Sommerbrodt has published an article, in which he relates the results of various experiments which he had conducted with the object of showing the connection which exists between pulmonary phthisis and certain primary affections of the larynx. The following conclusions are drawn from his experiments:

1. Chronic inflammation of the larynx and the upper part of the trachea in rabbits constantly induces pulmonary disease.

2. This disease is totally different from those which manifest themselves usually in rabbits, or which are produced experimentally, and consists in purulent peri-bronchitis, which, as is well known, ultimately brings on destruction of the lung, or pulmonary phthisis.

3. Consequently, purulent peri-bronchitis is an intermediate condition between primary ulcers of the larynx and pulmonary phthisis, and this is equally applicable to man.—*London Lancet*.

POISONING BY NITRATE OF SILVER.—As there are but two or three fatal cases of poisoning by nitrate of silver on record, we extract the following from the *Public Record*, of Philadelphia, for December 3: "Dr. Edward Petzold, of New York, lately applied a piece of nitrate of silver, better known as lunar caustic, at the end of a quill, to the throat of Charles Sternall, a child, in a case of inflammation. The nitrate of silver slipped from the quill down the child's windpipe, and entered the stomach. Its fearful effects were immediately apparent. The child was in agony, and died after the coatings of the stomach had been completely burned away."

THE EFFICIENCY OF ENEMATA.—Gustav Simon has succeeded in demonstrating that a stream of water forced into the rectum by means of a syringe may be made to penetrate the entire length of the large intestine, and possibly extend also into the small intestine. His experiments were performed upon two separate patients, each of whom happened to have a fistulous opening in the ascending colon, near its junction with the cæcum.—*Archiv für Klinische Chirurgie*; from *Boston Medical and Surgical Journal*.

CASE OF NEURALGIA OF THE TESTES CURED BY ELECTRICITY.—A young man free from all syphilitic disease experienced such intense pain in the testes that he urgently asked Dr. Felippi to perform castration. The case was carefully made out to be neuralgia, independent of any affection of the testicle or of any accumulation of fecal matter, and in five sittings the patient was entirely cured. Dr. Felippi made use of a weak and direct constant current.—*L'Imparziale*, No. 16, 1873.

ONYCHIA MALIGNA.—Rest and attention to the state of general health having preceded, the fungous growth is then burnt with strong nitric acid, washed with water, and poulticed. The relief is certain, and the repetition of the application seldom necessary. If there should be any trouble with the nail, the tender flesh may be protected by the insertion of a thin piece of compressed sponge, kept in its place by strips of plaster applied longitudinally to avoid compression.—*British Medical Journal*.

CHRONIC CATARRH OF THE PHARYNX TREATED BY GALVANO-CAUSTICS.—In an article published in *Deutsche Zeitschrift für Chirurgie*, Dr. Carl Michel, of Cologne, advocates the use of galvano-caustics in chronic catarrh of the pharynx. He mentions seventy cases in which he was entirely successful, and in many of which inhalations, cauterizations with nitrate of silver, employment of mineral waters, etc., had failed.

MISCELLANY.

ENORMOUS CUTTLE-FISH OFF NEWFOUNDLAND.—So much interest, popular and scientific, attaches to the subject of cuttle-fishes that we offer no apology for extracting the following from the *New York Tribune*: "It appears, from a letter written by the Rev. Mr. Harvey, of St. John's, Newfoundland, to Mr. Dawson, Principal of McGill College, Montreal, that on the 26th of October two fishermen who were out in a small boat observed some object floating on the water at a short distance, which they supposed to be a large sail or the débris of a wreck. On reaching it, one of the men struck it with his 'gaff,' when immediately it showed signs of life, and reared a parrot-like beak, which they said was as big as a six-gallon keg, with which it struck the bottom of the boat violently. It then shot out from about its head two huge, livid arms, and began to twine them round the boat. One of the men seized a small axe and cut off both arms as they lay over the gunwale, whereupon the fish backed off to a considerable distance and ejected an immense quantity of inky fluid, that darkened the water for a great distance around."

"The men saw it for a short time afterwards, and observed its tail in the air, which they thought to be ten feet across. They estimate the body to have been sixty feet in length and five feet in diameter, of the same shape and color as the common squid, and moving in the same way as the squid, both backward and forward. One of the arms which the men brought ashore was, unfortunately, destroyed; but a clergyman who saw it assured Mr. Harvey that it was ten inches in diameter and six feet in length. The other arm had six feet of its length cut off before leaving St. John's; the remainder, which measured nineteen feet in length, is but three inches in circumference, except at the extremity, where it broadens like an oar to six inches in circumference."

"The men estimated that they left about ten feet of the arm attached to the body of the fish, which would make it about thirty-five feet long. A trustworthy witness informed Mr. Harvey that in the winter of 1870 the bodies of two cuttle-fishes were cast ashore on the coast of Newfoundland, measuring forty and forty-five feet respectively."

SLIPPERY-ELM BARK AS A POISON.—A son, aged 15 years, of Samuel Winslow, near Brooklyn, Iowa, ate a quantity of slippery-elm bark. A day or two afterwards he was taken violently ill, and, four days from the time of eating the bark, died. On a post-mortem examination, his stomach was found full of the bark twisted into balls, the organs being too weak to digest it.—*Druggist's Circular*.

It is stated that Professor Owen has just discovered in the London clay, at Sheppey, a new fossil bird with teeth somewhat resembling those in the Australian hooded lizard. He concludes it to have been web-footed and a fish-eater. No evidence of true teeth had previously been known in any bird.

CHOLERA IN HUNGARY.—The *Lancet* states that the epidemic of cholera in Hungary, from its beginning in 1872 to its close in 1873, is said to have attacked not less than 433,000 persons, and of these killed upwards of 183,000.

DR. HENRY W. FULLER, well known for his papers on rheumatism, recently died in London, at the age of fifty-three.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

It is with an internal sense of pleasure and warm approval that I have read your vigorous onslaught against the favoritism and privileges which medical men of high professional status assume and appropriate to themselves with so much *sang-froid*.

The poor, struggling devils at the bottom of the tree are compelled to observe every nicety and shade of ethical and traditional law of medical manner and custom; and it is with thanks, warm and hearty, that *one of them* sends greeting to you for your efforts to make *all* observe alike, whether at the top or the bottom round of the ladder.

It would profit nothing to expose the dirty tricks and traps by which doctors endeavor to destroy one another, and especially their struggling brethren. The astounded public would only hold us all in greater contempt, and cause new and more ingenious means to be invented to haze the younger or less successful members. But there is one great, growing evil, that is destined to crush not only the struggling practitioner, but to embarrass the whole profession, and that is the multiplication of so many hospitals and dispensaries in which medical services and advice are freely given away.

Those at the top of the tree may care very little about this matter; nay, may, and *do*, encourage the formation of these institutions for all manner of general and special purposes, well knowing that the class of patients who frequent these places do not intrude into their consulting-rooms; whilst the poor struggler looks on with the pain of hope deferred at the long lines and swarms of patients,—a motley crowd, it is true, of

"Mongrel, pup, whelp, and hound,
And curs of low degree,"

even from which *he* is debarred "in order that the institution may be extended in usefulness."

Why is it, even in these hard times, when it has become necessary for the charitable to form associations for the relief of the distressed, and the distribution of fuel and food and clothing, that they have a natural desire to know whether the recipient is really deserving or not? Does not every poor body who deserves help have to get some one who is well known to endorse them before *he* or she can be supplied? Why? because fuel, food, and clothing have fixed and certain values, and are valued accordingly. Is medical advice of any value? One would not think so, to judge from the eagerness with which medical nincompoops struggle and lay pipe to secure appointments on the staff of dispensaries and every public place where they can bestow their advice to any one willing to receive it, without question, money, or price. Is *vox Populi vox Dei*? Then the people have only to take their cue from the doctors themselves, and place the proper value on the article so freely given away. If the doctors think their advice and services worth nothing, why should the people think otherwise? What follows? Is it any wonder the dear public regard the advice of quacks, from a piss-doctor* to a homœopath, as equal to that of the best educated and most scientific practitioner of our art? The people see that with every other trade and profession certain prices are asked and paid without question; but they notice a body of men with high-sounding titles anxious to give away *in public* the article they have to sell, yet asking a good round sum if it is desired *in private*; and they reasonably demur, *if the privacy is all that is to be paid for*.

It is said the poor have the gospel preached to them without money and without price! Is it true? Look critically at any of our large congregations, and count how many really poor there are present; and if present in any large numbers, will it not turn out upon investigation that the said poor mostly pay the pastor? It may be said, Ah, but there are the missions and the street-preaching, which are free to all. Is it really so? *Does not the preacher get paid by somebody?* If so, then it is not free in the sense in which medical services are, where *nobody* gets paid.

*Some years ago, a lot of scallawags went around the country pretending they could tell and cure any disease by simply *looking* at the urine of the patient; they were dubbed piss-doctors by the populace.

And of the law! if there were established all over the city inns of court, where a body of lawyers was assembled at certain hours every day to give out free opinions, how would it fare with that profession? Why, just as it now does with the medical; all respect for the opinion of a lawyer would cease, and chimney-corner lawyers would abound, just as quacks now do in medicine. The lawyers, like the members of every other trade and profession, are sharp enough to appreciate this, and make their opinion as comprehensive and valuable as that of Jack Bunsby; a sharp fee and cash on delivery are the watchwords, and hence no ancient crone or Washington's body-servant can upset *their ipse dixit*. But, in the medical world, how very easily are *our* opinions knocked into the mud! Only to-day, after a consultation with "a head-doctor" of a hospital, over a case of simple inflammatory rheumatism in which nearly all the prominent symptoms were so well marked that even a medical tyro could not err in the diagnosis, and after a full explanation of the case to the friends of the patient by both doctors, I was gravely informed by the mother of the lad that a neighbor had pronounced it to be a case of *relapsing fever*! and she feared the doctors did not understand the case. Shade of Hippocrates and Professor Paine! Is not this the experience of every medical man? and does it not tally with the value we set on our own opinions and services by making them so free to all? One can hardly look at a newspaper without having his attention called to some new institution for special or general purposes being established by Doctors Smith, Jones & Co. Poor fellows! *they* are not on any of the numerous staffs, and they will have a staff of their own if nothing better can be had.

And what is to prevent any or all of the smaller fry from following the example of the Pennsylvania Hospital, in advertising the names, offices, and residences of those Jeremy Diddlers? If these hospital doctors can have their names and residences emblazoned in the public print, no matter whether by their own doing or that of the hospital managers, why cannot the vulgar herd announce in print, in the biggest type, *their* ability to cure piles, retroflected uterus, and all the ills that flesh is heir to? Why should not *we* go about with our obstetrical forceps stuck in our coat-pockets, taking care that the long handles thereof be left prominently out, and strike with awe the common multitude? What is to hinder these said managers of the hospitals and dispensaries from insisting on their SERVANTS wearing a suit of livery à la Jeems Yellowplush? I cannot help wishing they would do so, and thus run the thing into the ground.

How is all this to be remedied? I answer, simply by the reasonable process adopted by all our charitable associations for the relief of the suffering poor, viz.: that we *demand* the same evidences of the worthiness and real poverty of the applicants before advice or services are rendered. If this simple remedy were adopted, there would be far less *material* for hospitals and dispensaries to help up at a rapid pace the medical exquisites of high social-status parentage; give a *fixed* and *certain* value to medical opinions, and place us all on a fair equality for the race which is before us.

VERTEX.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

At the stated meeting in January, the following officers and delegates were elected for the year 1874:

President—Dr. W. L. Atlee.

Vice-Presidents—Dr. Albert Fricke and Dr. J. E. Eshleman.

Recording Secretary—Dr. Henry Leaman.

Assistant Recording Secretary—Dr. Lemuel J. Deal.

Corresponding Secretary—Dr. William Goodell.

Treasurer—Dr. William M. Welch.

Censor—Dr. H. St. Clair Ash.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 27, 1874, TO FEBRUARY 2, 1874, INCLUSIVE.

BAILY, JOHN C., SURGEON.—Granted leave of absence for two months. S. O. 15, A. G. O., January 26, 1874.

BENTLEY, E., ASSISTANT-SURGEON.—Granted leave of absence for thirty days, with permission to apply for an extension of thirty days to the Adjutant-General of the Army. S. O. 11, Department of California, January 21, 1874.

TAYLOR, M. K., ASSISTANT-SURGEON.—Paragraph 1, S. O. 8, c. s., from these Headquarters, is revoked, and Assistant-Surgeon Taylor is assigned to duty at Austin, Texas. S. O. No. 11, Department of Texas, January 19, 1874.

HEIZMANN, C. L., ASSISTANT-SURGEON.—Assigned to duty as Post Surgeon at McPherson Barracks, Nebraska. S. O. 10, Department of the Platte, January 23, 1874.

SATURDAY, FEBRUARY 14, 1874.

ORIGINAL COMMUNICATIONS.

A NEW THEORY CONCERNING THE PROXIMATE CAUSE OF THE ENLARGEMENT OF THE PROSTATE BODY [GLAND].

BY JOHN STOCKTON-HOUGH, M.D.,

Philadelphia.

SIR HENRY THOMPSON* says, "Next in importance to the discovery of some unquestionably successful means for the cure of enlarged prostate, perhaps, indeed, equal to it, would be a recognition of those circumstances which stand in the relation of cause, remote and proximate, to this remarkable affection."

With a view of determining the proximate cause, the writer has incidentally collected a few facts which seem to explain in some cases the cause of the enlargement of the prostate, and begs to offer them to corroborate the opinion advanced which attributes the condition to developmental causes.

Albinus,† and Cowper‡ as well, described a small sac in the region of the caput gallinaginis in the male urethra, which was afterwards described by Morgagni,§ and called the sinus pocularis, which Weber|| called the *uterus masculinus*, and Huschke¶ *utriculus prostatica* or *virilis*, and which is believed by the majority of celebrated anatomists of the present day to be the analogue of the genital canals (uterus and vagina) of the female. Among these may be mentioned Ackermann, Schlichting, and Guthrie.

The male uterus (prostatic vesicle), according to Simpson, is "often prematurely enlarged and disproportionately developed in different kinds of hypospadiac and hermaphroditic malformations."**

The acquired enlargement of the prostate is principally found in quite old men, at the close of their sexual life, and has been often observed in animals whose testicles have been injured or extirpated.

According to Greve,†† "the prostate gland as well as the vesiculæ seminales become augmented as much as a third in their volume in consequence of the operation" of castration in the horse.

Hunter proved from his experiments that the vesiculæ seminales of the side on which he extirpated the testicle do not undergo diminution in size. The enlargement of the vesiculæ seminales in cases of the removal of the testicles would seem to give weight to M. Geoffroy St.-Hilaire's observation,—viz., that the vesiculæ seminales are the analogue of the body of the uterus in the female.

Simpson‡‡ suggests that "some of the various diseased states attributed to enlargement, etc., of the third lobe of the prostate gland will yet be found to be morbid states of the prostate vesicle. To the minds of some, the investigations of 'the diseases of the male uterus' would appear to be almost a paradox in thought and words."

Simpson evidently looks upon this enlargement as a morbid or diseased state, which is certainly developmental in its character, if a disease at all. The writer claims, however, that simple enlargement of the prostate often occurs without being in any wise a diseased or morbid state, any more than the growth of beard or non-development of the mammary glands in the female, or the absence of beard or development of these glands in the male, are diseased conditions.

In women who have passed the climacteric period the uterus often becomes diseased, but as often becomes atrophied by virtue of the cessation of the functional activity of the ovaries, following some physiological law of development. Velpeau says, "In old age the ovaries are atrophied, become *elongated*, and of a very irregular shape; the womb tends again back to the original size; the cavity of its body becomes so contracted that the stricture which connects it with the neck is sometimes found to close it completely up, as has been very judiciously observed by M. Mayer, and as I have often observed."

My friend and sometime colleague, Dr. A. C. W. Beecher, in a recent letter called my attention to the case of a lady who died at the age of eighty-nine years from cancer of the pylorus, in whom the uterus showed marked diminution in size, it being but two inches in length, one and a half inches in breadth at the largest part of the body, and one-half inch thick at this part. The body of the organ was flaccid, wrinkled, and very inelastic, and felt as if the vessels had undergone some degree of ossification, as had other arteries in the body. The intra-vaginal portion of the cervix was entirely obliterated. An incision through the anterior wall showed the arbor vitæ very distinctly. The os internum was tightly closed, and the cavity of the uterus contained a small quantity of jelly-like matter. The body was smaller proportionally than the cervix, comparing it with the menstruating womb. The ovaries were shrivelled, being almost as hard as cartilage, and had numerous small cysts over their surfaces. The uterus, ovaries, and appendages did not weigh one-third as much as the ordinary healthy organs of a menstruating woman. This woman had borne several children. The date of the cessation of the menses is not known.

The release of the domination of the testicles in males, either by castration, disease, or obliteration, we know allows of reversion towards the female type in secondary sexual characters; and why may not this be accompanied by a corresponding development of the morphological analogue of the female uterus and other undeveloped female organs

in the male, by mere exhaustion of their procreative powers by age? May not, then, the enlarged prostate of the aged, or indeed at any time of life, be considered as an attempt to develop a uterus, rather than an actual diseased condition and as indicating a loss of sexual capacity?

The enlargement of this organ under these circumstances might be ascribed to *retrogressional development*, if we may use such an expression.

Sir Astley Cooper* says, "The enlarged prostate is the consequence of age, and not disease."

Sir Charles Bell† gives no opinion as to the remote predisposing cause.

Sir Henry Thompson is of the opinion that the nature of the enlargement is not a morbid one, but usually a hypertrophy of the normal tissue of the organ. Mr. Ellis appears to be of the same opinion.

Though there can be but little doubt that this organ is sometimes the seat of morbid action, yet "malignant disease of the prostate is undoubtedly a rare affection."‡

Professor Gross, so ripe in experience as a teacher and practitioner of surgery, and consequently so well qualified to judge of the nature of the affections of this organ, says, in speaking of enlargement of the prostate, "The complaint seems to depend essentially upon hyperplasia of the unstriped muscular and fibrous elements which constitute the chief bulk of the prostate, and which, during the progress of age, are liable to new growth similar to that so often witnessed in the uterus of elderly females. . . . Hence hypertrophy of the prostate cannot be regarded as an adenoma, in the true sense of the term."§

Dr. John Ashhurst, Jr.,|| also calls attention to the analogy between the "fibrous and fibro-muscular growths (myomata) met with in the uterus" with those found in the prostate body.

Concerning the impropriety of considering the prostate as a glandular body, recent anatomists and surgeons of the highest authority are agreed that the prostate is not a gland, but a muscular organ; and the writer would suggest the name of *prostate body* as a suitable name for this organ.

Mr. George Viner Ellis¶ says that "The prostate is a muscular body, consisting of circular or orbicular involuntary fibres." He therefore considers that "the propriety of calling that body a gland is rendered doubtful."

Sir Henry Thompson, in speaking of the enlargement or tumors of the prostate, says, "In all, however, the basis is *muscular fibre*." Concerning the analogy between the prostate and the uterus, he says, "Analogies of a remarkable kind exist between the characters and relations of these three forms of tumor and those which affect the uterus."***

Velpeau†† also insists upon this analogy; and indeed it is, we are persuaded, the almost universal opinion of surgeons and anatomists of the highest authority of the present day.

Sir Henry Thompson, in his "Jacksonian Prize Essay" on stricture of the urethra (1852), stated it as his "belief that its [the prostate's] function was that of a *muscle*, and that it performed an important part in the apparatus designed to expel the seminal fluids." Mr. George V. Ellis‡‡ is of the same opinion.

In another place,§§ though he regards the cause of enlargement as by no means determined, yet he says, "It is an interesting circumstance that the prostate (male homologue of the uterus) should exhibit analogies in many points of view with the latter organ in regard to its tendency to overgrowth. The most obvious explanation, and the conclusion which, after a careful examination of the subject, is that which appears to me better supported than any other, seems to be offered in the simple fact, now completely established, that the structure in both [prostate and uterus] is exceedingly prone to develop among its component elements minute, independent, isolated formations, possessing an organization identical with itself," etc., etc.

Civiale|||| declines to accept the speculative analogy between the prostate and the uterus, and, indeed, combats, in an equally futile way, most of the causes hitherto assigned, except, perhaps, calculus of the bladder.

Some authors look upon the enlargement of the prostate as a mere accidental circumstance, as the appearance of cancer for instance; while others go so far as to regard it as an almost invariable concomitant of old age.

Sir Benjamin Brodie says, "When the hair becomes gray and scanty, when specks of earthy matter begin to be deposited in the tunics of the arteries, when a white zone is formed at the margin of the cornea,—at this same period the prostate gland usually, I might perhaps say invariably, becomes increased in size."¶¶

Sir Everard Home*** also regarded the enlargement of the prostate as a natural attendant of old age.

The latest and most distinguished of these knighted††† celebrities in the treatment of this condition—Sir Henry Thompson—considers that "It may be regarded as established by the facts before the Society, that enlargement of the prostate, so far from being a change natural to old age, is an exceptional condition."††† This opinion is principally based upon 43 specimens of the prostate from

††† It is noticeable as a curious coincidence that most of the knighted surgeons have given us essays, articles, or monographs on this condition: witness Sir Astley Cooper, Sir Everard Home, Sir Charles Bell, Sir Benjamin Brodie, Sir James Fergusson, Sir James Paget, Sir Henry Thompson, Sir James Y. Simpson; and in our country, though we have no knights in orders, yet of knights indeed, Gross, Pancoast, Mott, and Buck are equally worthy.

men 50 years of age and above, examined by this distinguished author. Of these 43 specimens, two were unusually small, 14 were enlarged, or 32 per cent. The average age in the nine cases in which the enlargement was slight was 64 years. In the five cases where the enlargement was notable the average age was 69 years, none being younger than 61. The average age of persons of 50 years and upwards not affected by enlargement was 64 years.

Dr. John Cockburn Messer, in his "Report of the Condition of the Prostate in Old Age, founded on the Dissection of 100 Specimens in Individuals over Sixty Years of Age,"* says that 35 per cent. of them were enlarged, 20 per cent. abnormally small, and 45 within the limits of normal weight. Where the gland was normal, of those above sixty years of age the average age was 76.2 years; where it was enlarged, 75.2.

He concludes that "This enlargement, which is found in 35 per cent. of all prostates after sixty years of age, is produced principally by hypertrophy of the fibrous tissue which naturally exists in the organ."

Dr. John W. Lodge, at the suggestion of Professor Gross,† examined 312 cases, with the following results:

Of 23 men aged from 40 to 50 years, 2, or 8.69 per cent., had hypertrophy of the prostate; of 94 men aged from 50 to 60 years, 18, or 19.14 per cent., had hypertrophy, and 3 atrophy, of the prostate; of 113 men aged from 60 to 70 years, 27, or 23.89 per cent., had hypertrophy, and 2 atrophy, of the prostate; of 64 men aged from 70 to 80 years, 11, or 17.18 per cent., had hypertrophy of the prostate; of 15 men aged from 80 to 90 years, 3, or 20 per cent., had hypertrophy of the prostate; of 3 men aged from 90 to 100 years, none had hypertrophy or atrophy of the prostate. Thus, in 289 men aged from 50 to 100 years, 59, or 20.45 per cent., had hypertrophy of the prostate.

Sir Henry Thompson (*op. cit.*, p. 67) calls attention to the fact "that among the twenty-nine unaffected were individuals of greater age than among the affected portion. . . . The period of life between 55 and 65 is that during which the affection is most commonly developed. I have never been able to meet with any instance of its occurrence before 50 years of age. On the other hand, it appears rarely to commence after 70. Where it exists, the disease has generally made considerable progress before 70 or 75."

This author seems to regard the fact of the affected having a lower average age than the unaffected as favoring his conclusion that enlargement, "far from being a change natural to old age, is an exceptional condition" (*ubi supra*). In our opinion, this fact favors the developmental theory of enlargement; for *what is life but developmental death, progressional in its ante-mature stage, and retrogressional in its post-mature stage?* If this be true, as we fully

believe it to be, those who died earliest reached maturity soonest, and, as a consequence, acquired enlargement of the prostate, the developmental accompaniment of old age, earlier than those who were more slow in maturing (developing, dying) and for this reason were, on an average, less aged at death.

All men do not lose their procreative power at the same age: indeed, some do not lose it at all. Hence, all do not have enlargement at the same age, or, dying before they are affected by a declension in this particular, do not have it at all. There is much greater disparity in the ages of men at the cessation of the procreative faculty than among women.

It is well known that the females of many kinds of birds, after they have lost the faculty of reproduction from age or other cause, but principally the former, assume some of the secondary sexual characters of the male, as the plumage, voice, habit, etc. Though the reproductive functions probably cease before death in a majority of female birds, yet this phenomenon is exceptional, and not confined in its appearance to any uniformity in age. So it is with the prostate: the subjects of enlargement are exceptional, and not limited to uniformity in age.

Those authors who contend that enlargement of this body is not due to venereal excesses‡ found their argument on the fact that very chaste men sometimes have the enlargement, and, moreover, it does not occur in men in the prime of life, when they would be most likely to indulge to excess in venery.
